Exchange Rate Misalignments at World and European Levels

a FEER Approach

Se-Eun Jeong[†], Jacques Mazier[‡] and Jamel Saadaoui[§]

Abstract

Since the mid-1990s, we observe an increase of world current account imbalances. These imbalances have only been partially reduced since the burst of the crisis in 2007. They reflect, to some extent, exchange rate misalignments, an issue which has been frequently studied in the literature. However, imbalances, which have reinforced in the 2000s, are also important inside the Euro area. This analysis cannot be reduced to simple estimates of euro misalignment at the world level because of specific constraints that exist for each member of the Euro area. This article aims to examine to what extent intra-European imbalances reflect exchange rate misalignments for each “national euro”.

Classification JEL: F31, F32

Key words: Equilibrium Exchange Rate, Current Account Balance, Macroeconomic Balance

1. Introduction

Since the mid-1990s, world current account imbalances have increased significantly and have only been partially reduced since 2007. These imbalances reflect inequalities in terms of growth, savings and investments and exchange rates misalignments. Exchange rates misalignments have been studied in details in the literature using two main approaches: the Behavioral Equilibrium Exchange Rate (BEER) and the Fundamental Equilibrium Exchange Rate (FEER). They generally concluded that the dollar was overvalued and that the euro undervalued during the first half of the 2000s. While these misalignments have been gradually reduced, the yuan remains undervalued since the second half of the 1990s.

However imbalances and misalignments also concern monetary unions like the Euro area, where intra-regional imbalances have increased since the early 2000s. Indeed, while the current account of the Euro area has remained close to equilibrium, the German surplus contrasts with the growing deficits of France, Italy and Spain.

The objective of this paper is to examine to what extent the intra-European imbalances reflect exchange rates misalignments specific to each Euro area members. Consequently, this analysis cannot be reduced to the simple estimate of euro misalignments but it must also deals with misalignments of each “national euro”.

For this purpose, a FEER approach is implemented. The FEER is defined as the level of exchange rate which allows the economy to reach the internal and external equilibrium at the same time ([Williamson, 1983](#)). The internal equilibrium is defined as the full utilization of productive resources of one country without generating inflation pressures. The external equilibrium corresponds to a sustainable current account.

In a first step, using a simplified world trade model, FEERs are estimated for the main currencies (dollar, euro, yen, yuan and pound sterling). In a second step FEERs can be estimated for each country of the Euro area, using simple national models and linking the estimation of national FEERs to the multinational model to get bilateral misalignments of each “national euro”.

Our results confirm that exchange rate misalignments have been reduced since the mid-2000s at the world level, with the exception of the yuan which remains undervalued. Nevertheless, misalignments seem to be more important for each individual Euro area member than for the whole Euro area. Especially, the undervalued “euro mark” contrasts with the overvalued “euro franc” and “euro peseta”.

This paper is organized as follow. A second section summarizes the theoretical and methodological background. A third section presents the multinational model and the national models used to estimate the FEER. A fourth section gives estimates of the external and internal equilibrium. A fifth section presents estimates of the FEER for the main currencies (dollar, euro, yen, yuan and pound sterling) and for each “national euro”. A last section concludes.

2. Theoretical and methodological background

By definition, exchange rate misalignment is defined as the gap, in percentage, between observed exchange rates and equilibrium exchange rates. Yet, various methodologies can be used to estimate equilibrium exchange rates. In what follows, we present a summary of the main methodologies.

2.1. Equilibrium exchange rates methodologies

The PPP (Purchasing Power Parity) is the oldest one and simplest methodology to estimate equilibrium exchange rates. In order to explain the movements of equilibrium exchange rates, this simple approach only relies on the relative prices. It ignores, however, other structural factors and seems too schematic, even when completed by a Balassa-Samuelson effect.

Beyond the PPP hypothesis, three main theories of equilibrium exchange rates can be distinguished: a) the Fundamental Equilibrium Exchange Rate ([Williamson, 1983](#)) and its recent developments ([Cline, 2008](#)), b) the Behavioural Equilibrium Exchange Rate which is an econometric approach ([Clark and MacDonald, 1998](#)) and c) the Natural Real Exchange Rate (NATREX) which tries to give a theoretical basis with a dynamic analysis ([Stein and Allen, 1997](#)). The BEER approach explains the exchange rate dynamic with some main variables (usually the net foreign assets, the terms of trade, the productivity, the oil prices) which influence the real exchange rate at long term.

A long term equation is first estimated by a co-integration method and then, using an error correction model, a short term equation is estimated. The exchange rate misalignments are simply measured by the gap between the observed exchange rate and its long run value. This econometric approach is rather easy to manage and gives useful results. But the theoretical basis can be regarded as underdeveloped and recent improvements have been mainly econometric and statistics.

The NATREX develops a theoretical model with a distinction between short, medium and long term. The NATREX is supposed to assure the equilibrium of the current account independently of cyclical factors and of speculative capital flows. The internal equilibrium is supposed to be reached. But, beyond these theoretical foundations, the estimation of the NATREX relies on a reduced equation which is not clearly linked with the original model. Like in the case of the BEER, the approach is based on econometric tools with variables added at short term without clear justification and with a long term value which can hardly be regarded as an equilibrium one. (see e.g. [Ahearne et al., 2007](#), [Bouveret et al., 2006](#)).

The FEER is defined as the exchange rate prevailing when the economy simultaneously reaches the external equilibrium (sustainable current account determined by structural parameters) and the internal equilibrium (full utilization of the productive potential). This approach is based on a structural model which mainly describes foreign trade relations and relates explicitly movements of exchange rates to internal and external imbalances. It has the advantage of focusing directly on structural parameters of each country. It allows for the estimation of equilibrium exchange rates of the different partners in a coherent manner by using a multinational trade model, which is rarely assured in the other approaches. Its limited linkages with the inter-temporal optimizing literature are often criticized but the FEER does not pretend to describe the modality of the return to the equilibrium. It searches only, for each period, to estimate the real misalignment induced by the internal and external imbalances in terms of comparative statics.

Despite the fact that each approach has its advantages and its drawbacks, we prefer the FEER approach because it is more explicitly articulated with the structural characteristics of each country and it ensures greater consistency of estimates across countries.

2.2. The FEER approach and the SMIM

The following analysis will be conducted in two steps: firstly at the level of the main currencies (dollar, euro, yuan, yen, and pound sterling), secondly at the level of each country of the Euro area for which an equilibrium exchange rate can be estimated for each “national euro”.

First, a multinational model describing the foreign trade of the United States, the Euro area, China, Japan, the United Kingdom and the rest of the world allows us to calculate the main currencies' equilibrium exchange rates. It is well known that in a *n-country model* there are only *n-1 independent bilateral exchange rates*, because the first country's exchange rate (usually the dollar) is the numeraire against which the others are compared. Consequently, there is an overdetermination problem in the FEER approach, as there are more equations (current account targets) than unknowns (exchange rates). The solution often chosen is to use the rest of the world as a residual, i.e. its equilibrium exchange rate does not achieve its current account target.

The methodology adopted in this paper will be different. Inspired from the symmetric matrix inversion method (SMIM) ([Cline, 2008](#)), the six countries will be treated symmetrically by

carrying out 6 sets of estimates with the multinational model (each country will be treated as a residual). A simple average of the results can be obtained. However, there is a high degree of consistency in the alternative estimates of equilibrium exchange rates for any given country across the 5 solutions in which the current account target of the country in question is included (designated OCI for own country included). Conversely, there is sometimes a great difference between the average value and the value that is obtained in the resolution where the target country or area is not included (designated OCE for one country excluded). Consequently, the solution adopted in this paper is to use as the estimate the average of equilibrium exchange rates obtained from all the solutions, except the one for which the country in question is regarded as a residual (OCI).

Secondly, for each country of the Euro area, an equilibrium exchange rate will be estimated using a simple national model of the foreign trade with the rest of the world. The equilibrium exchange rate will be defined, as previously, as the exchange rate compatible with the internal and external equilibrium of each country. It has been shown that, for a relatively small country like the European ones at the world scale, a national model gives results which are very close to the ones obtained with a multinational model ([Jeong and Mazier, 2003](#)).

This methodology is a synthesis of several methodologies of the FEER ([Borowski and Couharde, 2003](#), [Jeong and Mazier, 2003](#)) and that of the SMIM. It improves previous works on several levels. We construct a simpler model to use than in the early work of Williamson, who used large econometric models. The foreign trade model takes fully account of the interdependencies among main economies. The rest of the world is modeled explicitly, which ensures consistency of worldwide results. Another advantage of our approach is that the case of small and large countries is clearly differentiated, as it will be explained more in detail. In this sense, our approach is more manageable than using a model of thirty-five countries with a simple reduced equation between current account and real effective exchange rate for each countries ([Cline and Williamson, 2008](#)). Moreover, our model incorporates the effects of the foreign debt service and of the oil prices on the current account.

This method follows works on the medium-term determinants of current accounts ([Faruqee and Debelle, 1998](#), [Chinn and Prasad, 2003](#)), the equilibrium current account are determined by estimating structural determinants of current account (demographic features, developmental stage, deficits, net foreign assets, etc...) relying on panel regression techniques. It avoids using an ad-hoc approach which is often used, but seems less well founded. Sensitivity tests are conducted in order to assess the sensitivity of the results to adopted targets (the current account target, the internal equilibrium) and to values of the parameters (the price-elasticities).

3. Macroeconomic Modeling

3.1. The multinational model

The model describes the trade structure of the main countries or areas, namely, the United States, Japan, China, the Euro area and the United Kingdom (export volume equation (1), import volume equation (2), export price equation (5) and import price equation (6)). For the rest of the world, export and import volumes are determined as the residual of the equations of world trade equilibrium in value (3) and in volume (4) while their export and import prices are determined in the same manner as for other trading partners. We notice that this multinational specification gives a full account of the interdependence effects in volume and prices of exports and imports of all countries. We incorporate a consumer prices equation (7) to take into account the feedback effect between the consumer prices and the import prices. The real effective exchange rate is defined relatively to the consumption prices. Finally, the current account is defined as in equation (9) except for the rest of the world.

With usual notations, the model is written as:

Foreign trade volume equations

$$\begin{aligned}
 \text{Export volume equation} \quad X_i &= X_{0i} DM_i^{\eta_{X_i}} COMPX_i^{\varepsilon_{X_i}} & (1) \\
 DM_i &= \prod_{j \neq i} M_j^{\alpha_{ij}} \\
 COMPX_i &= (PMX_i / PX_i)
 \end{aligned}$$

$$\text{Import volume equation} \quad M_i = M_{0i} DI_i^{\eta_{M_i}} (PD_i / PM_i)^{\varepsilon_{M_i}} \quad (2)$$

With $i = 1 \sim 5$ {1 = Japan, 2 = China, 3 = U.S., 4 = Euro area, 5 = U. K.}

World trade equilibrium in value and in volume

$$\text{Equilibrium in value} \quad \sum_i PX_i X_i = \sum_i PM_i M_i \quad (3)$$

$$\text{Equilibrium in volume} \quad \sum_i X_i = \sum_i M_i \quad (4)$$

With $i = 1 \sim 6$ {6 = Rest of the World}

Price equations

$$\begin{aligned}
 \text{Export price equation} \quad PX_i &= PMX_i^{\alpha_{X_i}} P_i^{1-\alpha_{X_i}} & (5) \\
 PMX_i &= \prod_{j \neq i} (E_j PX_j / E_i)^{\lambda_{ij}}
 \end{aligned}$$

$$\begin{aligned}
 \text{Import price equation} \quad PM_i &= PMM_i^{\alpha_{M_i}} PD_i^{1-\alpha_{M_i}} & (6) \\
 PMM_i &= \prod_{j \neq i} (E_j PX_j / E_i)^{\mu_{ij}}
 \end{aligned}$$

$$\text{Consumer price equation} \quad PD_i = PM_i^{\alpha_i} P_i^{1-\alpha_i} \quad (7)$$

$$\text{Real effective exchange rates} \quad R_i = \prod_{j \neq i} [(PD_j / E_j)^{v_{ij}} / (PD_i / E_i)] \quad (8)$$

With $i = 1 \sim 6$ {6 = Rest of the World}

Current account

$$\text{Current account} \quad B_i = PX_i X_i - PM_i M_i - E_i P_{pet} M_{pet_i} - i_i E_i F_i \quad (9)$$

With $i = 1 \sim 5$ {1 = Japan, 2 = China, 3 = U.S., 4 = Euro area, 5 = U. K.}

The multinational model variables are defined as follows: X , non-oil exports in volume; DM , world demand in volume; DI , internal demand in volume; $COMPX$, export prices competitiveness; PX , export prices; PMX , competitor export prices; M , non-oil imports in volume; PM , import prices; PMM , world import prices; PD , consumer prices; P , producer prices; E , nominal bilateral exchange rates vis-à-vis the dollar; R , real effective exchange rates; B , current account; i , interest rates for its external debt; F , net external debt; P_{pet} , oil price; M_{pet} , net oil import.

We notice that in the model the dollar plays the role of numeraire ($E_3 = 1$) and the bilateral exchange rates of other currencies against the dollar are written as 1 dollar = E_1 yens = E_2 yuans = E_4 euros = E_5 pounds = E_6 monetary unities of the rest of the world.

In this framework, FEERs are defined as the real effective exchange rates compatible with the simultaneous realization of the internal and external macroeconomic equilibrium at medium term of each trading partner. The internal equilibrium means that actual output follows the potential production and the external equilibrium means that actual current account corresponds to the sustainable current account at medium term.

The model is written in logarithmic differential compared with the equilibrium, which directly calculates the extent of the misalignment. Variables in lower case correspond to the log differences of these variables, thus $e = dE / E = (E - E^e) / E^e$ for the bilateral exchange rate and $x = dX / X = (X - X^e) / X^e$ for other variables, except for current account $b = (B / PY) - (B / PY)^e$ where b represents the difference between the observed current account and the equilibrium current account as a percentage of GDP ([appendix 1](#)). The value of bilateral exchange rate misalignment (e) is given by solving the model in logarithmic differential.

On the whole, the multinational model comprises 35 endogenous variables (x, m, px, pm, pd for the six countries or areas and the five bilateral exchange rates e) for 35 equations (x, m, b for the five countries other than the rest of the world, px, pm, pd for the six countries and the two world trade equilibrium equations). The real effective exchange rates are calculated *ex post* using bilateral exchange rates and consumer prices.

The producer prices p are supposed to be at equilibrium, which means that we do not include a price-wage loop in our model. The two exogenous variables are the internal and the external equilibrium gap (di and b , respectively).

In logarithmic differential form, the degree by which the economy deviates from its internal and external equilibrium determines the degree of misalignments of its currency. On the one hand, the degree of deviation of internal demand is measured by $di = (DI - DI^e) / DI^e$ where DI^e = equilibrium internal demand. This equilibrium internal demand is linked to the potential production. On the other hand, the gap between actual current account and equilibrium one, as a percentage of GDP, is given by $b = (B / PY) - (B / PY)^e$. This variable, which quantifies the deviation from the external balance, is central in determining the exchange rate misalignment. The model allows us to calculate an “equilibrium exchange rate” of the rest of the world (e_{rom}), coherent with the equilibrium exchange rates of the five other countries, but not compatible with its current account target (B_{rom}^e). This rest of the world’s current account target is equal, at the world level, to the opposite of the sum of the five other countries’ current account targets. However, we don’t use this target in this model since, as mentioned previously, the rest world is used as a residual to ensure consistent estimates in real effective term.

In order to solve this problem, we use a methodology inspired by the SMIM ([Cline, 2008](#)). The six countries are treated symmetrically. Six sets of estimates are done successively with the multinational model (each country will be treated as a residual). A simple average of the results could be obtained. But it is preferable to use as an estimate of the equilibrium exchange rates the average obtained for all the solutions, except the one for which the country in question is regarded as a residual (OCI).

3.2. The national model

For each country of the Euro area, it is possible to estimate a specific equilibrium exchange rate which is different from the euro’s one. Although the bilateral exchange rate of the euro against the dollar is the same for all the Euro area’s members, the nominal and real effective exchange rates of each European country are different, due to important differences in their foreign trade structures. Furthermore, in spite of progress in European economic and financial integration, European countries are still marked by large differences at the structural and institutional levels. This justifies the estimation of equilibrium exchange rates for each Euro area’s members.

This can be done using a foreign trade model for each European country in which the world

demand and world trade prices are exogenous. As explained above, it is not necessary for a relatively small country like the European ones at the world scale, to use a multinational model to estimate equilibrium exchange rates. The following equations specify the trade volume and price equations for a small country facing world economy. The equation (14) describes the formation of current account.

$$X_i = X_{0i} D_i^* \eta_i^{\alpha_i} (E_i P_i^* / P X_i)^{\varepsilon_i} = X_{0i} D_i^* \eta_i^{\alpha_i} R_i^{(1-\alpha_i)\varepsilon_i} \quad (10)$$

$$M_i = M_{0i} D_i^* \eta_i^{\alpha_i} (P_i / P M_i)^{\varepsilon_i} = M_{0i} D_i^* \eta_i^{\alpha_i} R_i^{-\alpha_i \varepsilon_i} \quad (11)$$

$$P X_i = (E_i P_i^*)^{\alpha_i} P_i^{1-\alpha_i} = R_i^{\alpha_i} P_i \quad (12)$$

$$P M_i = (E_i P_i^*)^{\alpha_i} P_i^{1-\alpha_i} = R_i^{\alpha_i} P_i \quad (13)$$

$$B_i = P X_i X_i - P M_i M_i - E_i P_{pet} M_{pet} - i_i E_i F_i \quad (14)$$

$$R_i = [E_i P_i^* / P_i] \quad (15)$$

$$P_i^* = P X_i^* = \prod_{j \neq i} (P X_j / E_j)^{\lambda_{ij}} \cong P M_i^* = \prod_{j \neq i} (P X_j / E_j)^{\mu_{ij}} \quad (16)$$

With $i = 1 \sim 9$ {1 = France, 2 = Germany, 3 = Italy, 4 = Spain, 5 = Austria, 6 = Finland, 7 = Ireland, 8 = Netherlands, 9 = Portugal} and $j = 1 \sim 6$ {1 = Japan, 2 = China, 3 = U.S., 4 = Euro area - country i , 5 = U. K., 6 = Rest of the World}

The national model variables are defined as follows: X , non-oil exports in volume; D^* , world demand in volume; P^* , world prices; PX , export prices; M , non-oil imports in volume; DI , internal demand in volume; PM , import prices; P , consumer prices; E , bilateral exchange rate against the dollar; R , real effective exchange rates; B , current balance; i , interest rates for its external debt; F , net external debt; P_{pet} , oil price; M_{pet} , net oil import.

Solving this simplified model in logarithmic differential form gives r , misalignment of “national euro” in real effective terms ($r = d \text{Log} R = dR / R = (R - R^e) / R^e$):

$$r_i = \frac{\left[\left(\left(b_i / \mu_i T_i (1 - \sigma_{petx_i} - \sigma_{x_i}) \right) + \eta_i m_i d_i - \eta_i x_i d_i^* \right) \right]}{\left((1 - \alpha_i) \varepsilon_i + \varepsilon_i m_i \alpha_i + \alpha_i x_i - \alpha_i m_i \right)} \quad (17)$$

Where $\sigma_{petx} = E P_{pet} M_{pet} / P X X$, ratio of net oil imports on non-oil exports and $\sigma_x = i E F / P X X$, ratio of foreign debt service on non-oil exports.

The FEER approach focuses on real effective exchange rates. However, the nominal bilateral exchange rate against the dollar of each “national-euro” can be more intelligible. By using the equation (15), we can find out e , the degree of misalignment in bilateral nominal terms; the partner countries’ misalignments are given by the previous multinational model:

$$e_i = r_i + \sum_{j \neq i} \lambda_{ij} (p x_j - e_j) \quad (18)$$

We can also compute the effective exchange rate misalignments based on consumer prices:

$$r c_i = (1 - \alpha_i \mu_i) r_i + \sum_{j \neq i} v_{ij} (p d_j - e_j) - \sum_{j \neq i} \lambda_{ij} (p x_j - e_j) \quad (19)$$

3.3. Foreign trade elasticities

Without doing original econometric work, trade equations are taken from existing estimations realized with specifications close to the standard model presented before. We use especially long-term elasticities. Considering the uncertainties surrounding the estimations, sensibility tests to elasticities modifications are provided in the paper.

Table 1: Foreign trade elasticities for the multinational model

		<i>Price elasticity</i>				<i>Demand elasticity</i>	
		ϵ_x	ϵ_m	α_x	α_m	η_x	η_m
<i>China</i>	<i>Dées 1999</i>	0.71	1.02	0.56	0.66	0.75	1.04
	<i>Brillet 2000</i>	0.66	0.46	0.85	0.60	1.00	0.98
<i>U.K.</i>	<i>MIMOSA 1996</i>	0.70	1.33	0.07	0.59	0.87	1.82
	<i>Wren-Lewis 1998</i>	1.26	0.22	0.71	0.75	0.91	2.00
<i>Japan</i>	<i>MIMOSA 1996</i>	1.26	1.47	0.19	0.56	1.01	1.50
	<i>NIGEM 1997</i>	1.19	0.61	0.24	1.00*	1.00	1.69
	<i>Wren-Lewis 1998</i>	1.36	1.16	0.16	0.78	0.91	1.20
<i>U.S.</i>	<i>MIMOSA 1996</i>	0.91	1.44	0.09	0.50	1.04	1.56
	<i>NIGEM 1997</i>	0.52	0.61	0.00	1.00*	1.00	2.52
	<i>Wren-Lewis 1998</i>	0.96	1.35	0.19	0.55	1.12	2.00
<i>Euro area</i>	<i>ECB 2004</i>	0.50	0.81	0.50	0.51	1.00	2.77**
	<i>Hervé 2000</i>	1.39	0.30	0.75	0.64	1.05	1.06

* Import prices aren't estimated econometrically in the NIGEM model

** Estimated with a negative temporal trend

The elasticities of the MIMOSA model for Japan, the United States and the United Kingdom (close to those of Wren-Lewis), those of Dées for China and those of Hervé for the Euro area are taken for our simulation. The price elasticities are rather in accordance with the generally admitted hierarchical position of countries in the world trade. The relatively weak value for China could be surprising but might be explained by the particular nature of the Chinese trade. The trade model of China was estimated for the period 1985-1998 and for the first half of the 1980s the role of exchange rates in exports and imports is considered as little significant. Notice also that, Japanese and American exporters turn out to be largely price maker. For European countries, the selected elasticities are those of the MIMOSA model for France, Germany and Italy. For other European countries, the elasticities are derived from a previous contribution on interdependencies and adjustments in the European Union ([Mazier and Saglio, 2008](#)).

4. External and internal equilibrium at medium term

4.1. Estimation of equilibrium current account

As the current account equals the difference between domestic saving and investment (i.e. the saving-investment balance), the current account developments are examined from the perspective of the medium and long run determinants of saving and investment behaviors ([Faruqee and Debelle, 1998](#), [Chinn and Prasad, 2003](#)). According to these authors, the main determinants of

the current account at medium term are: the demographic characteristics, such as, the dependency ratios of dependent populations relative to the working age population, which is expected to exert a negative influence, with a higher dependency ratio leading to more spending; the net foreign asset, which is expected to have a positive effect, due to the capital income resulting from it; the government budget balance, with a public deficit having a negative effect on the current account, but this effect may be regarded as a simple accounting one which has not to be introduced.¹ Finally, we introduce a short-term effect, the output gap, since a higher utilization of production capacity leads to a deterioration of the current account. Yet, this last variable will be eliminated in the simulation of the equilibrium current account.

The equations of current account are estimated with panel data for 1980-2003 period and for two groups of countries. In a medium term perspective, we use non-overlapping four years average of annual data ([Lee et al., 2008](#)).

$$CA_{it} = a_i + a_t + \beta_0 + \beta_1 ISNFA_{it} + \beta_2 CDR_{it} + \beta_3 ODR_{it} + \beta_4 OG_{it} + \varepsilon_{it} \quad (20)$$

The variables of equation (20) are defined as follows: *CA*, current account as % of GDP; *ISNFA*, initial stock of net foreign assets at the beginning of each period of 4 years as % of GDP; *CDR*, child dependency ratio, population under the age of 15 years as % of population aged 15 to 64; *ODR*, old dependency ratio, population over the age of 65 years as % of population aged 15 to 64; *OG*, output gap in % of the potential production. The sources of the different variables are presented in [appendix 2](#). One group is composed of 19 industrial countries (Australia, Austria, Canada, Denmark, Finland, France, Germany, Ireland, Italy, Japan, Netherlands, New Zealand, Norway, Portugal, South Korea, Spain, Sweden, the United Kingdom and the United States) and will be used for determining the current account targets of the United States, Japan, the Euro area, the Euro area's members and the United Kingdom. The other group, composed of 20 emerging economies (Argentina, Brazil, Chile, China, Colombia, Ecuador, Egypt, India, Indonesia, Malaysia, Mexico, Morocco, Pakistan, Peru, Philippines, South Africa, Sri Lanka, Thailand, Tunisia and Turkey), will be used for determining the current account target of China.

The results of unit root tests are presented in [appendix 3](#). As it can be seen, we reject the null hypothesis of non-stationarity in all the series.

For industrialized countries, the estimated coefficients of equation (20) are on the whole significant with the predicted signs (Table 2) in different specifications. The dependency ratios are not highly significant, although they are the best theoretically justified variables. Output gap turns out to have negative effects on current account. Country effects raise the determination ratio. On the whole the cross section specification with country fixed effects seems the most relevant and is adopted in order to calculate the equilibrium current account.

Results for emerging countries are less conclusive than those for industrial countries, as in the case of other empirical studies ([Chinn and Prasad, 2003](#)). As previously, the coefficients are on the whole significant with predicted signs in the different specifications, with some exceptions (Table 3). Comparing cross section specification with the fixed effects and the pooled OLS, the former has a higher determination ratio, but the net foreign asset has a negative sign, which can hardly be explained. Consequently, panel OLS specification is adopted to estimate equilibrium current accounts for emerging countries.

¹ There are other variables, such as the openness ratio, which plays negatively, a higher openness meaning a greater possibility of assuring the debt service in the future, or the relative real GDP per capita, which exerts a non linear influence according to stages of development. We tried these variables, but results were not significant enough. Moreover, relative GDP per capita is evaluated non stationary by most of tests.

4.2. The simulated equilibrium current balances

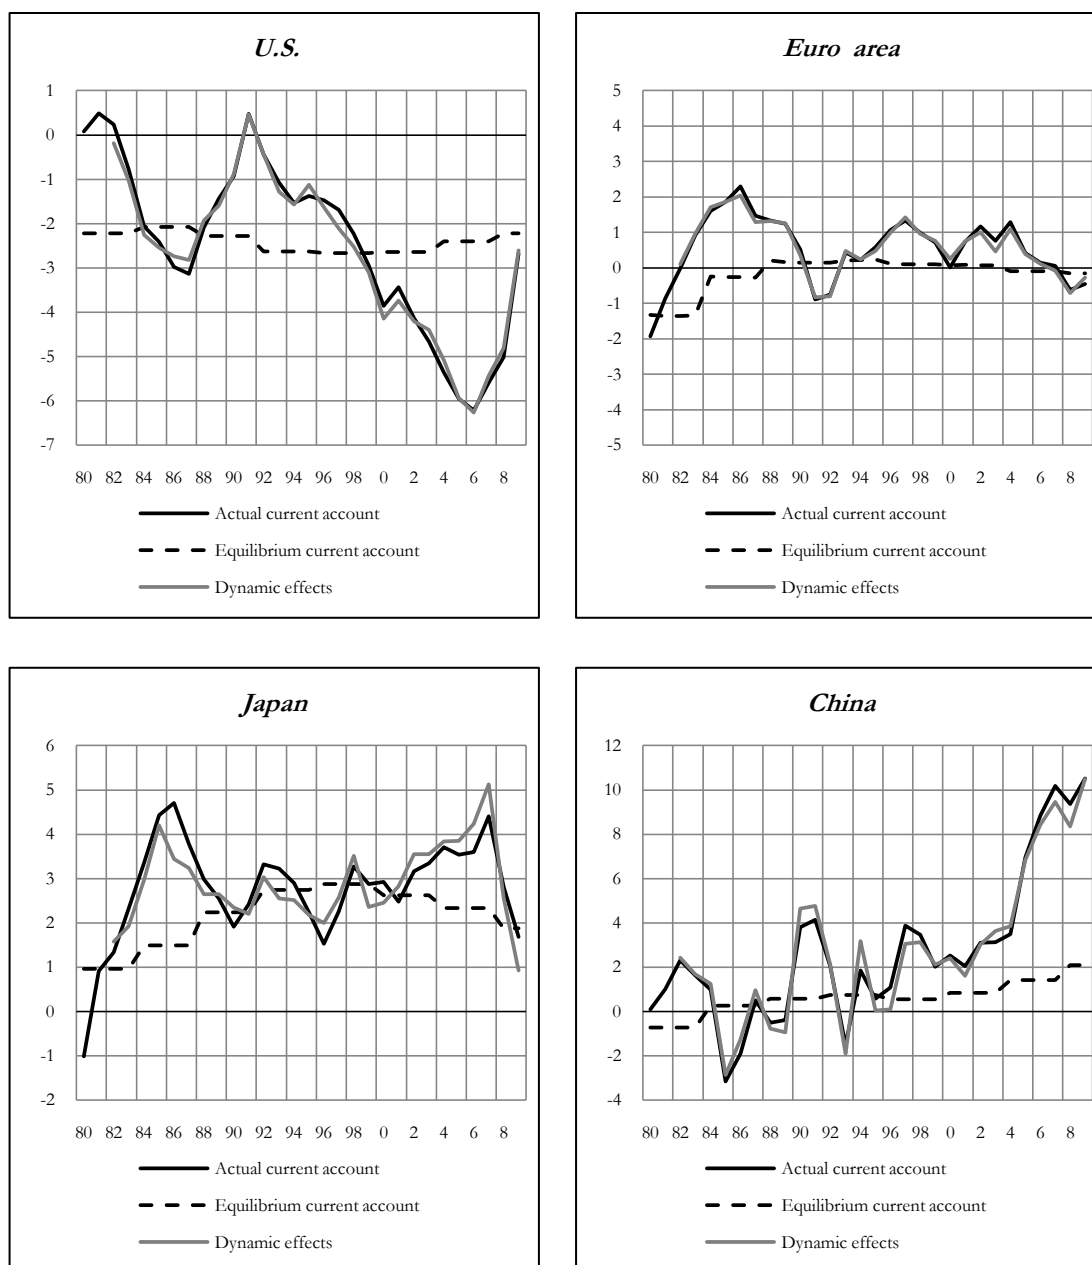

In simulating equilibrium current balances, we use the value of initial stocks of net foreign asset at the beginning of each four years period's and four years average values of dependency ratios and exclude output gap in order to remove short-term effects. Figure 1 shows the observed and equilibrium values of the current account for the main countries analyzed in the multinational model. Figure 2 gives the current account for the main euro area's members.

As seen, for the United States, the current account target is between -2 and -3% of GDP over the period. In several approaches on international imbalances, the target of -3% of GDP is selected for the U.S. current account deficit in the medium term (Ahearne et al., 2007). The simulated target for the current account deficit of the United States thus appears consistent with the

approaches that set the standard deficit on an ad-hoc basis.

Japan has experienced contrasting trends. Its equilibrium current account balance improved until the mid-1990s under the effect of improving its net external position resulting from surpluses' accumulation. Then there is a degradation of the Japanese equilibrium current account balance due, mainly, to a sharp increase in the old dependency ratio (ODR) which reduces national savings since it increases the share of inactive whose saving ratio is weak.

Figure 1: Actual and equilibrium current accounts of the main industrialized countries (in % of GDP)

(Source: authors' calculation, International Monetary Fund (World Economic Outlook, April 2009) for the observed current account as % of GDP, forecast for 2009)

China has an equilibrium current account close to zero % of GDP during the 1980s and the first years of 1990s, which seems coherent with the policy adopted by Chinese authorities that wanted to avoid the resort to large external debt. Since the mid-1990s, the equilibrium current account

shows an improvement to reach 2% of GDP in 2008. In this evolution the improvement of net external position and the decreasing of the child dependency ratio (CDR) play a positive role.

Figure 2: Actual and equilibrium current accounts of the main Euro area's members (in % of GDP)

(Source: authors' calculation, International Monetary Fund (World Economic Outlook, April 2009) for the observed current account as % of GDP, forecast for 2009)

Since the mid-1990s, the equilibrium current account balance of the Euro area is close to zero with a slight improvement over the early 1980s thanks to a growing external position. The amplitude of current imbalances in the euro area (as a whole) is weak compared to those observed in other major world economies. However, this “balanced” situation in the Euro area mask a great heterogeneity for each member of the Euro area. The Spanish, French and Italian current account deficits contrast, in recent years, with surpluses in Germany while their equilibrium current account balances are less in deficit. Since the mid-1990s, the equilibrium current account of France has improved thanks to more favorable demographic evolutions. By

contrast, the German equilibrium current account has returned to 0% of GDP as a result of the aging of the German population. The equilibrium current account of Italy and Spain, increased in the 1980s thanks to net external position improvement but they have deteriorated (in Italy) or stabilized (in Spain) around - 2% of GDP, again due to a substantial aging of the population.

A last correction should be specified. In the theoretical framework of the fundamental equilibrium exchange rates, the whole difference between the observed current balance and the equilibrium one must not be interpreted entirely as an external disequilibrium. This difference is partly due to delayed effects of exchange rates variations that have not yet occurred entirely, but should be taking into account in the estimation. This correction is made using the dynamic structure of external trade equations. Previous figures show observed and corrected current accounts with equilibrium ones.

4.3. The estimation of internal equilibrium

The internal equilibrium is defined as the state of full utilization of productive resources, without inflation pressures. For sake of simplification, a restrictive approach, limited to the measure of the potential output, is adopted. This approach of internal equilibrium seems less suited for emerging countries like China, where the concepts of potential output and full employment raise many problems, particularly because of the extent of regional imbalances and hidden underemployment in rural areas (Bouveret et al., 2006). It must be regarded as a first step, which seems, however, sufficient at this stage. Indeed, as we shall see, the results are slightly sensitive to the estimates of the output gap. Different methods can be employed in calculating potential production and the corresponding output gap. For industrialized countries, we take the values estimated with production function by the OECD². This approach relies on estimated productions functions and a measure of the available productions factors in the country. It demands more informations and more hypotheses regarding economic mechanisms than other simpler approaches, but is less mechanical, and is theoretically more relevant.

For developing countries, we calculate output gap by using the Hodrick-Prescott filter on real GDP over the period 1970-2013³. However, a study in depth on this issue found that output gaps of East Asian countries estimated by several methods are similar for the period 1975-2000 (Gerlach and Yiu, 2004). In addition, our sensitivity tests show that errors in output gap estimation do not disrupt the whole conclusion. In the case of China, an increase of 1% in output gap leads to less than 1% of undervaluation.

5. Equilibrium exchange rates and misalignments

5.1. Estimates of FEER for the main economic partners

With the internal and external equilibrium previously estimated, the multinational model for the main economic partners is used six times to produce misalignments in terms of real effective exchange rates ($r = d\text{Log}R = dR / R = (R - R^*) / R^*$) and nominal exchange rate against the dollar ($e = d\text{Log}E = dE / E = (E - E^*) / E^*$), each country playing successively the role of residual country without its own current account target. The final solution is obtained by making an average of the 5 runs in which the current account target of each country is included (designated OCI for own country included).

² Economic Outlook, OECD, December 2008.

³ As it is known, this filter has certain disadvantages. It does not define well the output gap at the beginning and at the end of samples. It tends to neglect the structural breaks and the regime shifts. For prolonged slowdowns it deviates too much from a production function gap. We use the Hodrick-Prescott filter with a lower smoothing parameter than that of industrialized countries to take into account that the business cycle is shorter in emerging countries.

This allows determining undervaluations ($e > 0$ and $r > 0$) or overvaluations ($e < 0$ and $r < 0$) for the dollar, the euro, the yen, the yuan, the pound sterling and the rest of the world's currency over the period 1994-2009. The results are presented in table 4. Figures 3 and 4 show the evolution of the observed and equilibrium exchange rate over the period, in real effective and nominal bilateral against the dollar terms.

Table 4: Undervaluation ($e > 0$ and $r > 0$) or overvaluation ($e < 0$ and $r < 0$) for Japan, China, the U. S., the Euro area, the U. K. and the rest of the world (in %)

(Source: authors' calculations, forecast for 2009)

In real effective terms, the dollar appeared undervalued in the middle of the 1990s (around 9%). Yet, this undervaluation decreased with the dollar's real appreciation and the American currency became overvalued (11% in 2001). Since then, in spite of its real depreciation, the dollar appeared more and more overvalued (reaching 30% in 2005 and 2006). This reflected the growing American imbalances and the structural loss of American competitiveness which, was illustrated by an even stronger real depreciation of the dollar's equilibrium exchange rate. After the crisis erupted in 2007, the real overvaluation of the dollar has been reduced and may reach 8% in 2009⁴.

The euro real effective exchange rate's evolution is rather opposite to the dollar's one. From the mid-1990s to 2000, the euro has depreciated in real effective terms but remained close to its equilibrium value, which depreciated also, reflecting the problems of European competitiveness during this period. Since 2000, the euro became undervalued in real terms (7% in 2001) in spite of its real appreciation, thanks to painful structural adjustments, mainly in Germany, which induced a real appreciation of the euro equilibrium exchange rate. With ongoing real revaluation, the euro real undervaluation has declined and has been replaced from 2005 by a slight overvaluation.

⁴ Forecast based on the World Economic Outlook, International Monetary Fund, April 2009.

In spite of its real appreciation, since 1994, the yuan has been undervalued in real effective terms (16% in 1998). This result is explained by the real revaluation of its equilibrium exchange rate, reflecting the important progress of the Chinese competitiveness. This undervaluation has been temporarily reduced after the Asian crisis and the large devaluations of most of the East Asian competitors.

From 1994 to 2001, the yen was overvalued relative to its equilibrium value in real effective terms (9% in 1999). From 2001, the real effective depreciation of the yen has encouraged the emergence of a real undervaluation (11% in 2007) helped to support exports during this period. With the real effective appreciation of the yen since 2007, this undervaluation has disappeared and been replaced by a slight overvaluation.

Figure 3: Actual and equilibrium real effective exchange rates (2000 = 100)

(Source: authors' calculations, Bank for International Settlements for the real effective exchange rate (annual average of monthly data), partial data for 2009)

In nominal bilateral term against the dollar, rather convergent observations can be done. The

euro, the yen and the pound sterling were overvalued from 1994 to 1998, although the first two have depreciated. This reflected the undervaluation of the dollar during the second half of the 1990s. The yuan was the only exception with an undervaluation against the dollar, although attenuated by the Asian crisis's consequences. After 2000 all the currencies became undervalued against the dollar (22% for the euro, 47% for the yuan, 36% for the yen and 18% for the pound in 2006) in spite of the dollar depreciation. This reflected the growing imbalances of the U.S. economy which have led to a depreciation of the equilibrium exchange rate of the dollar. Following the crisis, the undervaluation has disappeared and all the currencies are close to their equilibrium value in 2009, except the yuan which remains undervalued.

Figure 4: Actual and equilibrium bilateral exchange rate against the dollar (2000 = 100)

(Source: authors' calculations, OECD for bilateral exchange rates, partial data for 2009)

In spite of some differences in the methodology, a comparison with other estimates is possible. For 2008 our results are close to those of Cline (Table 5). If, in both cases, the FEER framework

is used, Cline's model has 35 countries, a simpler analysis of the foreign trade for each country and no structural approach of the current account equilibrium. Instead, it is simply supposed that external imbalances should not exceed 3% of GDP (in absolute value) in the medium term, which allows building a scenario of current account targets for the 30 non-oil exporting countries. For 2009, results are more divergent, as Cline's results give a stronger real overvaluation of the dollar, which has an incidence on all the estimated nominal bilateral misalignments against the dollar. But these results are provisional and rely on different forecasts for 2009. Specifically, we have retained the IMF forecast of the US current deficit (-2.8% of GDP)⁵ whereas Cline has used a specific model to assess the U.S. current account deficit in the medium term (Cline and Williamson, 2009). He selected a forecast of the U.S. deficit of about 6% which give a stronger overvaluation.

Table 5: Comparison with Cline's estimates (in %)

<i>REER</i>		<i>USA</i>	<i>EU</i>	<i>CHN</i>	<i>JPN</i>	<i>UK</i>

(A positive number indicates an undervaluation. Conversely, a negative number indicates an overvaluation)

5.2. European disparities

Beyond estimates of misalignments for the whole euro area, intra-European disparities must be examined in more details. The misalignments are not of the same magnitude at the level of each European country due to the important heterogeneity which remains significant. The two most obvious sources of heterogeneity regarding exchange rates are the foreign trade structure, which differs largely among European country, and the inequality between national rates of inflation, which is less important but not negligible. These two sources of heterogeneity explain the dispersion of effective exchange rates in nominal and real terms, as shown in Figure 5.

The first point to underline is that effective exchange rates are more stable at the level of each national country than at the level of the whole euro area because the importance of intra-European trade with fixed exchange rates stabilizes the effective exchange rate. Between 2001 and 2008 the euro appreciation has been more limited at the national level than at the whole euro area level. This function of stabilization of the euro is an important argument in favor of monetary unification.

The second point is the dispersion between countries. In nominal terms, Germany has suffered of the strongest appreciation since 2001, due to the importance of the extra-European trade for this country, while, on the contrary, the euro appreciation was more limited in Spain where intra-European trade occupies a larger share. For real effective exchange rates, which are crucial for

⁵ International Monetary Fund, World Economic Outlook, April 2009.

competitiveness, it is the opposite. The dispersion is more noticeable between countries, due to the divergence between rates of inflation. In this case, Germany suffered of the smallest appreciation, thanks to its low relative rate of inflation, while Spain has faced a stronger real appreciation.

Figure 5: Nominal and real effective exchange rates (2000 = 100)

(Source: Bank for International Settlements (annual average of monthly data), partial data for 2009)

These divergences have an important impact on growth and employment in each country. But European heterogeneity covers a larger set of factors, such as the quality of the international specialization, the non-price competitiveness parameters, the efficiency of the national system of innovation, the nature of wage relations or the characteristics of the financial system and its links with the productive sector. All these institutional forms indirectly influence national economic performances. In a sense, they are reflected in the level and evolution of equilibrium exchange rates as they can be estimated for each European country. Like in the case of the main currencies, the following tables present the overvaluation ($r < 0$, $e < 0$) or undervaluation ($r > 0$, $e > 0$) for each “national euro” for the period 1994-2009 in real effective terms (table 6) and bilateral terms against the dollar (table 7). Sensitivity tests are given in [appendix 4](#) to appreciate the dependency on the estimates of external and internal equilibrium and on the parameters of the trade model.

First, it appears that misalignments for each “national euro” are quite different from what is observed for the euro itself. Consequently, the constraints exerted on each European country by the euro exchange rate policy are very different.

Second, the relative position of each “national euro”, in terms of misalignments, is not permanent and can vary in the medium to long-run according to structural adjustments which affect each economy. The cases of Germany and France are interesting to examine first in that perspective. In the mid-1990s, the “euro-mark”, which was in fact the Deutschmark at that time, was overvalued (nearly 7% in real effective terms, around 18% against the dollar) because of the consequences of the German reunification. This required a substantial transfer of resources from West to East Germany, induced a drift of unit costs and significantly reduced the German external surplus. At the official launching of the euro in 1999 the “euro-mark” was still overvalued. This contrasted with the position of the global euro which, at that time, was close to equilibrium. Since the late 1990s, the German economy has realized a painful adjustment process by cost reducing and industrial restructuring with delocalization of activities. This strategy has

significantly slowed down economic growth in Europe during this period but helped to rebuild new foundations for German competitiveness. As a consequence, since the mid-2000s, the “euro mark” has become undervalued (around 18% in real effective terms, around 35% against the dollar) while the euro, for the whole area, became overvalued.

France is, for a large part, in an opposite situation. In the second half of the 1990s, the “euro franc” was undervalued (by almost 12% in real effective terms and against the dollar). France took advantage of the German economic difficulties and of its long run strategy of competitive disinflation. This situation did not last. Since the mid-2000s, the “euro franc” became more and more overvalued in contrast with a global euro close to its equilibrium value. This induced strong constraints on the French economy during this period and reflected structural problems of competitiveness which had remained unsolved since the 1990s. These problems had only been reduced by the German transitory difficulties following the reunification and by the disinflation strategy, which turned to be only a short term solution, without solving more structural handicaps.

(Source: authors' calculations, forecasts for 2009)

Spain and Italy are other interesting cases to examine. Following the devaluations that took place during the European Monetary System crisis, the peseta and the lira were undervalued during the second part of the 1990s (nearly 12% in real effective terms, less in bilateral terms against the dollar). But, like for the French franc, this did not last. After the launching of the euro, we observed an overvaluation of the “euro-peseta” and, to a lesser extent, of “euro-lira”, which has strengthened. This overvaluation reflected large inequalities of competitiveness inside the euro area. Actually constraints were less important in the case of Italy than in the case of Spain, with the housing bubble during the first half of the 2000s. The large overvaluation of the “euro

peseta” (over 50% in 2008, in real effective terms) was largely related to insufficient productivity and weaknesses in R&D in a context of unsustainable economic growth. Portugal is another case of Southern European economy affected by the overvaluation of its currency since the second half of the 1990s. With a weak productivity, a peripheral localization and a specialization in low costs products, the Portuguese economy has never succeeded to invert this situation within the constraints of the euro area.

(Source: authors' calculations, forecasts for 2009)

On the opposite, Ireland is an illustration of a catch up strategy which has been more successful, at least until the beginning of the 2000s. Until this period, the exchange rate has remained close to its equilibrium. But, since 2002, the Irish economic growth has become more unbalanced with the housing bubble, although the overvaluation of the “Irish euro” remained rather limited. This illustrates the fact that small opened economies generally suffer less of exchange rate misalignments, as it can be understood with the equation (17), where the openness ratio plays a key role. However, the Portuguese case shows that this general rule may suffer of exception in cases of larger unbalances due to structural weaknesses.

Netherlands, Austria and Finland, three small opened Northern and Alpine European economies, sometimes labeled as social-democrats, are the last cases to be examined. Netherlands and Austria have kept their exchange rates close to equilibrium during most of the period, although the Austrian currency was slightly overvalued during the second half of the 1990s, due to stronger connections with Germany. On the contrary, the Finnish mark was more undervalued during the second half of the 1990s (around 15% in real effective terms), thanks to a large devaluation after the crisis of 1991-1992. This undervaluation has been progressively reduced, but

preserved due to structural improvement of Finish external performances and to increasing R&D effort.

To sum up, beyond estimates of exchange rate misalignments of the euro, important disparities are observed between “national euros”. The euro misalignments do not represent a pertinent indicator for each national euro. The misalignments seem to be more important for each individual euro area member than for the whole euro area. More specifically, during the first half of the 2000s the undervalued “euro mark” contrasts with the overvalued “euro franc” and “euro peseta”.

6. Conclusion

Current account imbalances have increased dramatically since the mid-1990s and were only partially reduced since the burst of the crisis in 2007. These imbalances partly reflect exchange rates misalignments, a fact that has been studied extensively in the literature. But imbalances, which have increased in the 2000s, are also important inside the Euro area. This analysis cannot be reduced to simple estimates of euro misalignment at the world level because specific constraints exist for each national economy of the euro area. This paper has examined to what extent intra-European imbalances reflect exchange rates misalignments for each “national euro”.

A FEER approach has been followed, combining both our previous methodology and its recent improvements ([Cline, 2008](#)) in order to solve the problem raised by the treatment of the rest of the world. By relying on panel regression techniques, equilibrium current accounts have been estimated for the main countries and for each member of the euro area. A two-steps analysis has been adopted.

First, using a simplified world trade model, a FEER has been estimated for the main currencies. Our results have confirmed the overvaluation of the dollar and undervaluation of euro during the first half of the 2000s, which have been progressively reduced while a durable undervaluation of the yuan has remained since the second half of the 1990s.

Second, a FEER has been estimated for each European country of the euro area, using simple national models and linking estimates of the national FEER to the multinational model to obtain bilateral misalignments of each “national euro”. Results show that important disparities were observed between “national euros”. The misalignments appeared more important for each individual euro area member than for the whole euro area. During the first half of the 2000s, the undervalued “euro mark” has contrasted with the overvalued “euro franc” and “euro peseta”. Southern European countries have been more affected by overvaluation while small countries remained closer to exchange rate equilibrium.

More generally, the misalignments of each “national euro” have changed at medium-long run according to structural adjustments which occurred in each country. They have also been induced by asymmetric shocks (like after the German reunification during the 1990s) or specific growth regimes (like the housing bubble in Spain or Ireland in the 2000s).

Disparities between European countries had important consequences for the definition of economic policy at the EU level, since these countries were characterized by divergent forces. A durable overvaluation means a permanent handicap for the related economy which can be compensated only by painful adjustments (as was the case in Germany in the 1990s). To reduce these adjustment costs, there are no appropriate economic tools *at EU level*, as might be structural funds for new activities or sectors undergoing restructuring. This could justify the use of structural policies *at the national level*, to compensate temporarily negative misalignments effects, yet, these types of polices are in contradiction with the currently prevailing rules at Community level. A durable undervaluation means, on the contrary, an advantage that may disappear gradually without structural progress (as in France in the second half of 1990s) or may be used to improve the quality of international specialization through the R&D and policy incentives (e.g. Finland). In this perspective a cumulative advantage may be generated.

Lastly, these results for the 2000s lead us to note the similarities between the current situation of

misalignments within the euro area and the situation observed during the 1980s, within the European Monetary System, when the undervaluation of the Deutschmark was counterbalanced by the overvaluation of other European currencies ([Couharde and Mazier, 2001](#)).

(*** = Significant at 1%, ** = significant at 5% using the test statistic Im Pesaran Shin; the rejection of the null hypothesis (of the presence of unit root), leads us to reject non-stationarity of the series.)

Appendix 4: Sensitivity tests

Considering the existing uncertainties in the estimation of external and internal equilibrium and in the measure of trade elasticities, three kinds of sensibility tests have been performed:

- an increase of the target current balance of 1% of GDP (bc);
- an increase of the potential production of 1% (y^e);
- an increase of the export price elasticity of 20% (ε_x);
- an increase of the import price elasticity of 20% (ε_m).

Table 8: Sensitivity tests on real effective exchange rates (rc) (Absolute average of changes from the base simulation results)

	bc	y^e	ε_x	ε_m
<i>FRA</i>	0.0242	0.0049	0.0047	0.0048
<i>GER</i>	0.0116	0.0026	0.0051	0.0031
<i>ITA</i>	0.0101	0.0025	0.0011	0.0020
<i>SPA</i>	0.0176	0.0051	0.0101	0.0091
<i>AUT</i>	0.0107	0.0011	0.0022	0.0022
<i>FIN</i>	0.0100	0.0034	0.0061	0.0074
<i>IRL</i>	0.0038	0.0017	0.0021	0.0008
<i>NLD</i>	0.0044	0.0033	0.0014	0.0006
<i>PRT</i>	0.0184	0.0054	0.0079	0.0110

(Source: authors' calculation)

Several informations can be withdrawn from these results (Table 8):

- The sensitivity to the potential production is limited. A higher potential production and consequently an increased under-utilisation of production capacities lead to a more significant real overvaluation of the currency. The elasticity is between -0.1 and -0.5 meaning that an additional under-utilisation of 1% results in an increased overvaluation between -0.1% and -0.5%.
- The sensitivity to the current account target is moderate. An increase in the current account target that is a reduction of the gap b leads to an overvaluation of the concerned currency. The effect weakens as the GDP share of exports and the elasticity of current account to real exchange rate increase.

– The sensitivity to the export and import price elasticities also turns out to be small. On the whole higher export price elasticity leads to smaller changes in exchange rates to absorb the same amount of current account imbalances. Absolute average of results means the degree of lesser misalignments of exchange rates under higher price elasticity. This result is reassuring considering the existing uncertainties in the estimation of these parameters.

These sensitivity tests assure that the FEER approach provides rather robust results in spite of uncertainties in estimating the internal and external equilibrium and the parameters of trade equations.
