## Abstract

In this paper we compare two different variable selection approaches for linear regression models: *Autometrics* (automatic general-to-specific selection) and LASSO ( $\ell_1$ -norm regularization). In a simulation study, we show the performance of the methods considering the predictive power (forecast out-of-sample) and the selection of the correct model and estimation (in-sample). The case where the number of candidate variables exceeds the number of observation is considered as well. We also analyze the properties of estimators comparing to the oracle estimator. Finally, we compare both methods in an application to GDP forecasting.

**Key Words:** model selection, variable selection, GETS, *Autometrics*, LASSO, adaptive LASSO, sparse models, oracle property, time series, GDP forecasting.

## 1. Introduction

Econometric model selection is an interesting problem, for which many different solutions have been proposed. Traditionally, one can choose the set of explanatory variables using information criteria or prior information, but the total number of models to evaluate increases exponentially as the number of candidate variables increases.

Automatic variable selection is a topic that has been widely discussed in the recent econometric literature, and many techniques and methodologies have been proposed. Although these approaches have been mostly applied to economic data, either for forecasting or identification of the relevant variables of the model, it can be useful for modeling and forecasting any kind of data.

Several strategies for automatic model selection have been proposed over the years. Two notable approaches are the expanding or specific-to-general methods and the shrinkage or general-to-specific methods. Some examples of specific-to-general methods are stepwise regression, forward selection and the more recent RETINA (Perez-Amaral et al., 2003) and QuickNet (White, 2006). In the general-to-specific (GETS) category the most important methods are based on a model selection strategy developed by the LSE school ('LSE' approach), revised in *PcGets* (Hendry and Krolzig, 1999, and Krolzig and Hendry, 2001), and more recently in *Autometrics* (Doornik, 2009). Still among shrinkage methods, the Least Absolute Shrinkage and Selection Operator (LASSO), introduced by Tibshirani (1996), and the adaptive LASSO (adaLASSO), proposed by Zou (2006), have received particular attention.

Important work has been done in the comparison between different methodologies. Perez-Amaral, Gallo and White (2005) and Castle (2005) evaluated and compared *PcGets* (general-to-specific approach) and RETINA (specific-to-general approach). The two procedures present different goals: RETINA was developed with the aim of finding a model that has good out-of-sample predictive ability whereas *PcGets* selects a congruent dominant in-sample model, aiming to locate the DGP (Data Generating Process) nested within the GUM (General Unrestricted Model). Ericsson and Kamin (2009) compared and assessed the empirical merits of *PcGets* and *Autometrics*. Castle et al. (2011) considered how to evaluate model selection approaches and compared *Autometrics* to 1-cut approach, which consists in a GETS selection for a constant model in orthogonal variables, where only one single decision is required to select the final model.

Although all the recent literature in this field, no work has been done comparing the *PcGets*, or *Autometrics* (extension of *PcGets*), with the LASSO, or adaLASSO. In this paper, we compare these methods on linear regression models. In the simulation experiment we compare the predictive power (forecast out-of-sample) and the performance in the selection of the correct model and estimation (in-sample). The case where the number of candidate variables exceeds the number of observation is considered as well. The different model selection methodologies were compared varying the sample size, the number of relevant variables and the number of candidate variables. Finally we apply both methods to predict the quarterly US GDP on the period from 1959 to 2011.

The paper is organized as follows. In Section 2 we introduce and present the

model selection methodologies, algorithms, estimators and settings. Section 3 presents the Monte Carlo experiment, the simulation results and the comparison between *Autometrics*, LASSO and adaLASSO. Section 4 presents the application of the methodologies to US GDP forecasting. Finally, Section 5 concludes.

## 2. The Model Selection Techniques

### 2.1. *PcGets* and *Autometrics*

The main pillar of this approach is the concept of GETS modeling: starting from a general dynamic statistical model which captures the main characteristics of the underlying data set, standard testing procedures are used to reduce its complexity by eliminating statistically insignificant variables, checking the validity of the reductions at every stage to ensure the congruence<sup>1</sup> of the selected model.

Hoover and Perez (1999) were the first to evaluate the performance of GETS modeling as a general approach to econometric model building. To analyze the GETS approach systematically, Hoover and Perez mechanized the decisions in the GETS modeling by coding them in a computer algorithm. The most basic steps that such algorithm follows are:

1. Ascertain that the general statistical model is congruent (well specified).
2. Eliminate a variable (or variables) that satisfies the selection (i.e., simplification) criteria.
3. Check that the simplified model remains congruent.
4. Continue steps 2 and 3 until none of the remaining variables can be eliminated.

To eliminate the effect of the order of the variables elimination on the outcome of GETS modeling, Hoover and Perez (1999) considered many reduction paths from an initial general model. When searches lead to different model selections, encompassing tests and/or information criteria can be used to discriminate between these models.

Hendry and Krolzig (1999), and Krolzig and Hendry (2001) proposed improvements on Hoover and Perez's GETS algorithm. They develop and analyze an

---

<sup>1</sup> A congruent model should satisfy: (1) homoscedastic, independent errors; (2) strongly exogenous conditioning variables for the parameters of interest; (3) constant, invariant parameters of interest; (4) theory-consistent, identifiable structures; (5) data admissible formulations on accurate observations. For more details see Hendry and Nielsen (2007).

econometric model selection process, called *PcGets*, present in Ox Package. Using Monte Carlo simulation they studied the probabilities of *PcGets* recovering the data generating process (DGP), and they achieved good results. Campos et al. (2003) established the consistency of *PcGets* procedure. Hendry and Krolzig (2005) discussed how to produce nearly unbiased estimates despite selection.

*PcGets* opens up econometric analysis to non-expert users, freeing invaluable time for the user to think about the model, and interpret the evidence. The user is required to specify the general unrestricted model based in economic theory, and then let *PcGets*, and the computer, do the rest.

Doornik (2009) introduced a third-generation algorithm, called *Autometrics*, based on the same principles. The new algorithm can also be applied in the general case of more variables than observations. *Autometrics* uses a tree-path search to detect and eliminate statistically insignificant variables, thereby improving on the multi-path of *PcGets*. Such an algorithm does not become stuck in a single-path sequence, where a relevant variable is inadvertently eliminated, retaining other variables as proxies (e.g., as in stepwise regression).

Hendry and Krolzig (2005) advocated that *PcGets* and *Autometrics* can handle perfect collinearity<sup>2</sup>. One of the perfectly collinear variables would be initially excluded from the model, but the multi-path search allows the excluded variable to be included in a different path search, with another perfectly singular variable being dropped.

### **2.1.1. Methodology**

The GETS methodology embodies an algorithm that automatically selects empirical models from the observed data. The algorithm explores all feasible reduction paths from a very general starting point, eliminating insignificant variables until only the relevant variables are retained. *PcGets* and *Autometrics* has five basic stages: The first stage concerns the formulation of the GUM; the second determines the estimation and testing of the GUM; the third is a pre-search process; the fourth is the multi-path search procedure, in the case of *PcGets*, and tree-path search, in the case of

---

<sup>2</sup> Perfect collinearity denotes an exact linear dependence between variables; perfect orthogonality denotes no linear dependencies.

*Autometrics*; and the fifth is the selection of the final model.

We can say that *Autometrics* is an evolution of *PcGets* algorithm, as it is based on the same principles, but it can handle some problems that *PcGets* cannot: outlier detection and more candidate variables than observations. The following description sketches the main stages involved in *PcGets* algorithm: see Krolzig and Hendry (2001) for details.

### 1. *Formulation of the GUM*

The first stage of the algorithm requires the user to specify the general unrestricted model (GUM) based on subject-matter theory, institutional knowledge, historical contingencies, data availability and measurement information. The GUM must have stationary regressors. In this “prior specification” the aim of the user is the inclusion of potentially relevant variables, the exclusion of irrelevant effects, and to achieve orthogonality between regressors. The larger the initial regressor set, the more likely adventitious effects will be retained, but the smaller the GUM, the more likely key variables will be omitted. Further, the less orthogonality between variables, the more “confusion” the algorithm faces. Therefore, careful prior analysis remains essential.

### 2. *Mis-specification tests*

After estimating the GUM appropriately (ordinary least squares), the second stage tests the model for mis-specification. There must be sufficient tests to check the GUM for congruence (which implies that the model matches the evidence in all measured aspects), but not too many to induce a large type-1 error. If a mis-specification test (diagnostic test) is rejected, its significance level is adjusted or the test is excluded from the test battery during simplifications of the GUM. *PcGets* generally tests the following null hypotheses: white-noise errors, conditionally homoscedastic errors, normally distributed errors, unconditionally homoscedastic errors, and constant parameters.

### 3. *Pre-search reductions*

The next stage in selecting a congruent and parsimonious model involves a

pre-search simplification of the GUM. This pre-selection eliminates variables that are ‘highly’ irrelevant. The reductions are based on F-tests and t-tests of the variables ranked in order of their absolute t-values. The F-test tests for sequentially increasing blocks of omitted variables, using loose significance levels (larger than in the multiple reduction paths). The diagnostic tests are confirmed at every reduction stage to ensure congruence and the failure of a diagnostic test will terminate the reduction at that point. Having eliminated highly insignificant variables, we have a new GUM as the baseline for the remaining stages.

#### 4. *Multiple reduction paths*

The algorithm then implements a multi-path search, commencing from all feasible initial deletion points. The searches repeatedly filter for relevant variables using both t-tests and block F-tests. Again, diagnostic tests are checked at every reduction stage to ensure the congruence of the final model. The path is terminated when all variables remaining are significant, or a diagnostic test fails. The resulting model is the terminal model of that path.

#### 5. *Selection of the final model*

When all paths have been explored and all distinct terminal models have been found, encompassing can be used to test between them, with only the surviving, usually non-nested, specifications retained. The terminal models are tested against their union to find an undominated encompassing contender; rejected models are removed, and the union of the ‘surviving’ terminal models becomes a new GUM for another multi-path search iteration; then this entire search process continues and the terminal models are again tested against their union. If more than one model survives the encompassing tests, the set of mutually encompassing and undominated contenders is reported, and a unique final choice is made by the pre-selected information criterion.

The algorithm in *Autometrics* shares these characteristics and stages with the algorithm in *PcGets*. However, *Autometrics* (unlike *PcGets*) uses a tree-search method, with refinements on pre-search simplification and on the objective function. The tree-search procedure follows all feasible paths. For details see Doornik (2009).

In the pre-search stage, *Autometrics* can detect outliers using impulse dummies for all observations in a process known as impulse-indicator saturation (IIS). For more details see Hendry and Krolzig (2004) and Castle et al. (2012).

Allowing for a reasonable lag-length in the GUM or IIS, the researcher can be easily faced with a situation of more candidate variables than observations. In that case, *Autometrics* applies the cross-block algorithm proposed in Hendry and Krolzig (2004), which consist in:

1. dividing the set of variables into subsets (blocks), each of which contains less than half of the observations,
2. applying *Autometrics* model selection to each combination of the blocks (GUMs). The algorithm yields a terminal model for each GUM,
3. taking the union of the terminal models derived from each GUM, forming a new single union model.
4. If the number of variables in this model is less than the number of observations, model selection proceeds from this new union model (new unique GUM), otherwise, restarts the cross-block algorithm with the new set of variables.

In *Autometrics*, the user can set the maximum block size (-1: unlimited). By default, the maximum size is 128 variables.

### **2.1.2. Algorithm settings**

There are some important choices that the modeler should make before running the model selection algorithm. In *PcGets*, these choices concern the following:

1. Model strategy: Liberal or Conservative. The former seeks a null rejection frequency per candidate variable in a regression of about 5%, whereas the latter is centered on 1%. Hendry and Krolzig (2003) studied the difference between these two strategies. The Liberal strategy minimizes the non-selection probabilities and the Conservative minimizes the non-deletion probabilities.
2. Pre-search variables reduction (including lags): yes or no.
3. Fixed variables: Fixed variables are forced to always be included in regression, whereas free variables may be deleted by the algorithm.
4. Mis-specification tests and their significance levels (default is 0.01). Table 0 shows the diagnostic tests used by default in *PcGets*, recommended in Hendry and Krolzig (2003).

5. Information criteria for the final selection: AIC (Akaike’s Information Criterion), BIC (Bayesian Information Criterion) or HQ (Hannan-Quinn Information Criterion)<sup>3</sup>.

TABLE 0. MIS-SPECIFICATION TESTS

There are  $T$  observations and  $k$  regressors in the model under the null. The values  $T$  and  $k$  may differ across models and the value  $m$  may differ across statistics. By default, *PcGets* sets  $p=4$  and computes two Chow tests at  $\tau_1 = (0.5T)/T$  and  $\tau_2 = (0.9T)/T$ .

Test	Alternative	Statistic	Sources
AR 1- $p$ test	$p$ -th order residual autocorrelation	$F(p, T - k - p)$	Godfrey (1978), Harvey (1981, p.173)
ARCH 1- $p$ test	$p$ -th order autoregressive conditional heteroscedasticity	$F(p, T - k - p)$	Engle (1982), Engle, Hendry and Trumbull (1985)
Normality test	skewness and excess kurtosis	$\chi^2(2)$	Jarque and Bera (1980), Doornik and Hansen (1994)
Hetero test	Heteroscedasticity quadratic in regressors $x_i^2$	$F(m, T - k - m - 1)$	White (1980), Nicholls and Pagan (1983)
Chow ( $\tau T$ )	Predictive failure over a subset of $(1 - \tau)T$ obs.	$F((1 - \tau)T, \tau T - k)$	Chow (1960, p.594-595), Hendry (1979)

In *Autometrics*, which is part of the software PcGive version 12 or later, for the model strategy options (choice 1) the user can select a “target size”, which means “the proportion of irrelevant variables that survives the simplification process” (Doornik, 2008). The target size values that appear to approximate liberal and conservative strategies in *PcGets* are 5% and 1%, respectively.

For pre-search testing (choice 2), *Autometrics* allows the user to enable variables reduction and lag reduction separately. *Autometrics* calls the fifth choice tie-breaker, and, beyond the information criteria, the user can also set the algorithm to

<sup>3</sup> The information criteria are defined as follows:

$$AIC = T \times \left( \log \left( \frac{2\pi SSE}{T} \right) + 1 \right) + 2 \times k$$

$$BIC = T \times \log \left( \frac{SSE}{T} \right) + k \times \log T$$

$$HQ = T \times \log \left( \frac{SSE}{T} \right) + 2 \times k \times \log \log T$$

where SSE is the sum of squared errors,  $T$  is the sample size, and  $k$  is the number of parameters of the model: see Akaike (1974), Schwarz (1978), and Hannan and Quinn (1979).

choose the model with minimal number of regressors. By default, BIC is used as tie-breaker. The third and fourth choices above are identical for *PcGets* and *Autometrics*.

Besides these five choices, *Autometrics* also allows the user to enable outlier detection through dummy saturation.

As presented in the last sections, *PcGets* and *Autometrics* are similar methodologies, where the latter is more developed in many aspects. Ericsson and Kamin (2009) showed that, in several instances, *Autometrics* dominates *PcGets* by obtaining a more parsimonious model with a better fit whereas *PcGets* never dominates *Autometrics* in that sense. For all these reasons, we are going to use only *Autometrics* algorithm in the comparison exercise with LASSO and adaLASSO.

## 2.2. LASSO and adaLASSO

Shrinkage methods have become popular in the estimation of large dimensions models. Among these methods, the Least Absolute Shrinkage and Selection Operator (LASSO), proposed by Tibshirani (1996), has received particular attention because of the ability to shrink some parameters to zero, excluding irrelevant regressors. In other words, LASSO is a popular technique for simultaneous estimation and variable selection for linear models.

LASSO is able to handle more variables than observations and produces sparse models (Zhao and Yu, 2006, Meinshausen and Yu, 2009), which are easy to interpret. Moreover, the entire regularization path of the LASSO can be computed efficiently, as shown in Efron et al. (2004), or more recently in Friedman et al. (2010).

Despite all these nice characteristics, Zhao and Yu (2006) noted that the LASSO estimator can only be consistent if the design matrix<sup>4</sup> satisfies a rather strong condition denoted “Irrepresentable Condition”, which can be easily violated in the presence of highly correlated variables. Moreover, Zou (2006) noted that the oracle property in the sense of Fan and Li (2001)<sup>5</sup> does not hold for LASSO. To amend these deficiencies, Zou (2006) proposes the adaptive LASSO (adaLASSO).

---

<sup>4</sup> Design matrix: matrix of values of explanatory variables.

<sup>5</sup> Oracle property: the method both identifies the correct subset model and the estimates of non-zero parameters have the same asymptotic distribution as the ordinary least squares (OLS) estimator in a regression including only the relevant variables.

### 2.2.1. The LASSO and adaLASSO estimators

The LASSO technique is inspired in ridge regression, which is a standard technique for shrinking coefficients. However, contrarily to the latter, LASSO can set some coefficients to zero, resulting in an easily interpretable model.

Consider model estimation and variable selection in a linear regression framework. Suppose that  $\mathbf{y} = (y_1, \dots, y_T)'$  is the response vector, and  $\mathbf{x}_j = (x_{j1}, \dots, x_{jT})'$ , with  $j = 1, \dots, p$ , are the predictor variables, possibly containing lags of  $\mathbf{y}$ .

The LASSO estimator, introduced by Tibshirani (1996), is given by

$$\hat{\beta}^{LASSO} = \arg \min_{\beta} \left\| \mathbf{y} - \sum_{j=1}^p \mathbf{x}_j \beta_j \right\|^2 + \lambda \sum_{j=1}^p |\beta_j| \quad (1)$$

where  $\|\cdot\|$  denotes the standard  $\ell^2$ -norm, and  $\lambda$  is a nonnegative regularization parameter. The second term in (1) is the so-called “ $\ell_1$  penalty”, which is crucial for the success of the LASSO. The LASSO continuously shrinks the coefficients towards 0 as  $\lambda$  increases, and some coefficients are shrunk to exact 0 if  $\lambda$  is sufficiently large.

Zou (2006) showed the LASSO estimator does not enjoy the oracle property, and proposed a simple and effective solution, the adaptive LASSO, or adaLASSO. In LASSO the coefficients are equally penalized in the  $\ell_1$  penalty. In the adaLASSO each coefficient is assign with different weights. Zou (2006) showed that if the weights are data-dependent and cleverly chosen, then the adaLASSO can have the oracle property.

The adaLASSO estimator is given by

$$\hat{\beta}^{adaLASSO} = \arg \min_{\beta} \left\| \mathbf{y} - \sum_{j=1}^p \mathbf{x}_j \beta_j \right\|^2 + \lambda \sum_{j=1}^p \hat{w}_j |\beta_j| \quad (2)$$

where  $\hat{w}_j = 1/|\hat{\beta}_j^*|^\gamma$ ,  $\gamma > 0$ , and  $\hat{\beta}_j^*$  is an initial parameter estimate. As the sample size grows, the weights diverge (to infinity) for zero coefficients, whereas, for the non-zero coefficients, the weights converge to a finite constant. Zou (2006) suggests

using the ordinary least squares (OLS) estimator of the parameters as the initial parameter estimate  $\hat{\beta}_j^*$ . However, such estimator is not available when the number of candidate variables is larger than the number of observations. In this case, ridge regression can be used as an initial estimator.

### 2.2.2. Selecting $\lambda$ and $\gamma$

A critical point in the LASSO and adaLASSO literature is the selection of the regularization parameter  $\lambda$  and the weighting parameter  $\gamma$ . Traditionally, one employs cross-validation maximizing some predictive measure. In a time-dependent framework cross-validation becomes more difficult. An alternative approach that has shown good results is using information criteria, such as the Bayesian Information Criterion (BIC). Zou et al. (2007), Wang et al. (2007) and Zhang et al. (2010) study such method.

Zou et al. (2007) showed that the number of nonzero coefficients is an unbiased and consistent estimator of the degrees of freedom of the model, and proposed BIC for the LASSO. Shao (1997) indicated that in a classical linear regression, BIC perform better than cross-validation if the true model has a finite dimension and is among the candidate models. This motivated Wang et al. (2007) to compare LASSO with tuning parameters selected by cross-validation and BIC, and they showed that the LASSO with BIC selector performs better in the identification of the correct model. Finally, Zhang et al. (2010) study a more general criterion (Generalized Information Criterion) and show that the BIC is consistent in selecting the regularization parameter, i.e. enables identification of the true model consistently.

In this work, we will use the BIC as proposed in Wang et al. (2007), based in Zou et al. (2007), in the selection of both parameters  $\lambda$  and  $\gamma$ :

$$\text{BIC} = \log(\hat{\sigma}^2) + \frac{1}{T} \widehat{df} \log(T) \quad (3)$$

where  $\hat{\sigma}^2 = \text{var}(\mathbf{y} - \hat{\mathbf{y}})$ ,  $\hat{\mathbf{y}}$  is the prediction of  $\mathbf{y}$ , using the parameters estimates.  $\widehat{df}$  is the number of non-zero coefficients in the estimated model, and  $T$  is the number of observations. This selection method performs remarkably well in Monte Carlo simulations presented in the next section.

### 3. Simulation

In this section we are going to evaluate a Monte Carlo simulation in order to compare the *Autometrics*, LASSO and adaLASSO. To compare our simulation results we have followed Medeiros and Mendes (2013). The procedure used to solve LASSO is the *glmnet* function for Matlab, also used for ridge regression and elastic net. The *glmnet* procedure implements a coordinate descent algorithm. For more details, see Friedman et al. (2010).

Our goal is to compare the ‘size’ and ‘power’ of the model selection process, namely the probability of inclusion in the final model of variables that do not (do) enter the DGP, i.e. retention frequency of irrelevant variables, and retention frequency of relevant variables.

We also compare each estimator to the oracle estimator, which is the ordinary least squares (OLS) estimator in a regression including only the relevant variables. Finally, we compare the forecasting accuracy of the models selected by each model selection technique.

The data generating process (DGP) used is a Gaussian linear regression model, where the strongly exogenous variables are Gaussian white-noise processes.

$$y_t = \sum_{k=1}^q \beta_k x_{k,t} + \varepsilon_t, \quad \varepsilon_t \sim \text{IN}[0,1], \quad (4)$$

$$x_t = v_t, \quad v_t \sim \text{IN}_q[0, I_q] \text{ for } t = 1, \dots, T,$$

where,  $\beta$  is a vector of ones of size  $q$ .  $x_t$  is a vector of  $q$  relevant variables.

The GUM is a linear regression model, which includes the intercept, the  $q$  relevant variables of the DGP (4), and  $n-q$  irrelevant variables, which are also Gaussian white-noise processes. The GUM has  $n$  candidate variables and the constant, given by (5).

$$y_t = \pi_0 + \sum_{k_r=1}^q \pi_{k_r} x_{k_r,t} + \sum_{k_i=1}^{n-q} \pi_{k_i} x_{k_i,t} + \mu_t, \quad \mu_t \sim \text{IN}[0, \sigma^2] \quad (5)$$

where  $k_r$  is the index of relevant variables and  $k_i$  is the index of irrelevant variables.

We simulate  $T = 50, 100, 300, 500$  observations of DGP (4) for different

combinations of candidate ( $n$ ) and relevant ( $q$ ) variables. We consider  $n = 100, 300$  and  $q = 5, 10, 15, 20$ . The models are estimated by the *Autometrics*, LASSO and adaLASSO methods. The values of the tuning parameters of the LASSO and adaLASSO,  $\lambda$  and  $\gamma$ , are selected by the BIC, as in Section 2.2.2. The parameters settings in *Autometrics* are determined by the Liberal and Conservative strategies, i.e. we compare *Autometrics* with target size of 5% (Liberal) and 1% (Conservative). The rest of *Autometrics*'s settings are defined by default, as showed in Section 2.1.2.

### 3.1. Simulation results

In this section we present the results for the comparison of methodologies. We start by analyzing the properties of the estimators for the parameter  $\beta_1$  in (4), chosen arbitrarily. Figures 1-4 illustrates the distribution of the bias for the Oracle, *Autometrics* Liberal (Aut-L), *Autometrics* Conservative (Aut-C), LASSO and adaLASSO estimators for different sample sizes, number of candidate variables and number of relevant variables, with color lines shown in the color legend:

Color Legend for Figures 1-4

From the several plots, we can say that the bias and variance can vary greatly depending on the number of observations ( $T$ ) and the number of candidate variables ( $n$ ). Analyzing the plots along Figures 1 to 4, we notice that in all methodologies, in a general way, the bias and variance decrease with the increasing of  $T$ . Only by looking at the distributions we notice that both *Autometrics* (Liberal and Conservative) present the smallest bias and variance and the parameter estimates distribution is very close to the distribution of the Oracle estimator. Analyzing the LASSO and adaLASSO estimators distributions, it is evident that the latter is closer to the Oracle, but not as much as the *Autometrics* estimators. For  $T=500$ , all distributions are close to the Oracle except for the LASSO estimator, which is consistent with the theory presented earlier. For  $T=50$  and  $q=5$ , the distribution of each estimator approaches the distribution of the Oracle in an order: the closest is the Aut-C, followed by Aut-L,

adaLASSO and LASSO, in this order. Given both cases of  $n=100$  and  $n=300$ , we are facing the case  $T < n$ , and even in that extreme case, the bias and variance are relatively small. However, for the other values of  $q$ , the adaLASSO and LASSO distributions present fat-tails cause mainly by some outliers in the estimation, while the *Autometrics* distributions presents a nice behavior for all values of  $q$ . When  $T=300$  and  $T=500$ , the number of outliers reduces and the adaLASSO distribution gets closer to the Oracle, while the LASSO distribution still presents a greater bias.

FIGURE 1. Different combinations of candidate ( $n$ ) and relevant ( $q$ ) variables. The sample size equals 300 observations.

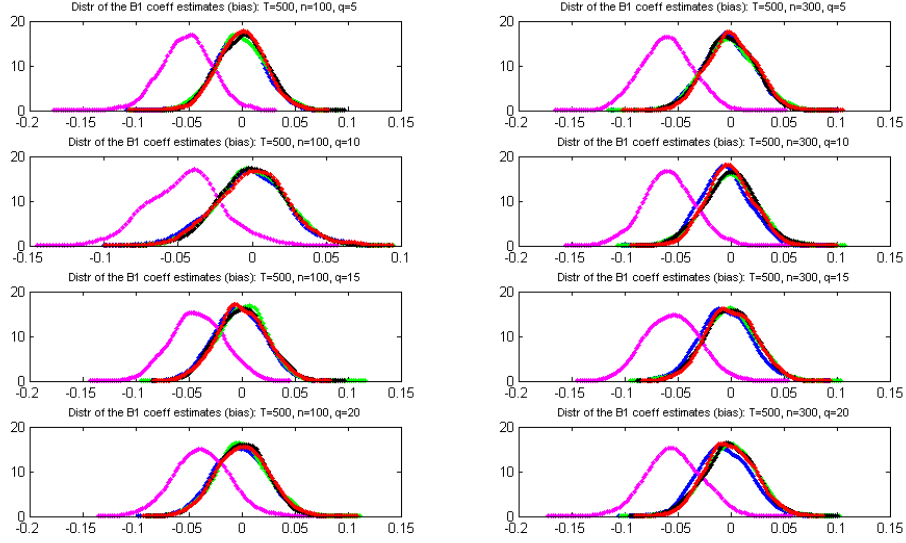

FIGURE 4. Distribution of the bias for the Oracle (red), *Autometrics* Liberal (green), *Autometrics* Conservative (black), LASSO (magenta) and adaLASSO (blue) estimators for the parameter  $\beta_1$  over 1000 Monte Carlo replications. Different combinations of candidate ( $n$ ) and relevant ( $q$ ) variables. The sample size equals 500 observations.

For a descriptive statistics of the parameters estimates, Table 1 shows the average absolute bias and the average mean squared error (MSE) for the *Autometrics* (Liberal), *Autometrics* (Conservative), LASSO and adaLASSO estimators over the simulations and the candidate variables, i.e.,

$$\text{Bias} = \frac{1}{1000n} \sum_{j=1}^{1000} \left( \sum_{i=1}^n |\hat{\beta}_i - \beta_i^{true}| \right) \quad (6)$$

$$\text{MSE} = \frac{1}{1000n} \sum_{j=1}^{1000} \left( \sum_{i=1}^n (\hat{\beta}_i - \beta_i^{true})^2 \right) \quad (7)$$

where

$$\beta_i^{true} = \begin{cases} 1, & \text{if } 1 \leq i \leq q \\ 0, & \text{if } q + 1 \leq i \leq n \end{cases} \quad (8)$$

is the vector of size  $n$  of “true” values of the parameters of the model.

We observe that both variance (MSE) and bias are very low, especially for the *Autometrics* (Liberal and Conservative) estimators. This is explained by the large

number of zero estimates. The adaLASSO estimator presents better results than the LASSO estimator. Looking at Figures 1-4, we observe that the bias and the MSE decrease with the sample size ( $T$ ) and increase with the number of relevant variables ( $q$ ).

Tables 2-5 present model selection results for each model selection technique. Panel (a) presents the fraction of replications where the correct model has been selected, i.e., all the relevant variables included and all the irrelevant regressors excluded from the final model; Panel (b) shows the fraction of replications where the relevant variables are all included; Panel (c) presents the fraction of relevant variables included; Panel (d) shows the fraction of irrelevant variables excluded; Panel (e) presents the average number of included variables; and Panel (f) shows the average number of included irrelevant regressors.

In a general analysis the selection performance of all methodologies improves with the sample size ( $T$ ) and gets worse as the number of relevant variables ( $q$ ) increases. Analyzing Panel (a), we notice a difference of behavior between *Autometrics* (Liberal and Conservative), and LASSO and adaLASSO methodologies. In LASSO and adaLASSO,  $T$  and  $q$  have a big influence in correct model selection, while the first two do not show a clear influence. Panel (b) and (c) show better results for both *Autometrics* when  $T=50$ . For  $T=100$ ,  $T=300$  and  $T=500$ , the true model is included almost every time and almost all relevant variables are included in the selected model. Analyzing Panel (d), it is clear that the fraction of excluded irrelevant variables is extremely high for all scenarios and methodologies. The number of included variables and, consequentially, the number of included irrelevant variables, increase with the number of candidate variables ( $n$ ) and decrease with the sample size, as shown in Panel (e) and (f). The *Autometrics* (Conservative) is the methodology that includes the less variables in the model selected.

TABLE 1. PARAMETER ESTIMATES: DESCRIPTIVE STATISTICS

The table reports for each different sample size, the average absolute bias and the average mean squared error (MSE), for each model selection technique, over all parameter estimates and Monte Carlo simulations.  $n$  is the number of candidate variables whereas  $q$  is the number of relevant regressors.

20	20.936	32.865	13.855	39.539	13.352	18.944	10.955	13.763

Table 6 shows the mean squared error (MSE) for one-step ahead out-of-sample forecasts for *Autometrics* (Liberal and Conservative), LASSO, adaLASSO and oracle models. We consider a total of 100 out-of-sample observations. As expected,

all methodologies improve their performance as the sample size increases, and the number of relevant and candidate variables decrease. For  $T=500$ , all methodologies has similar performance out-of-sample to the Oracle. In a general way, *Autometrics* (Conservative) presents the lowest MSE (closest to the Oracle).

TABLE 6. FORECASTING: DESCRIPTIVE STATISTICS

The table reports for each different sample size, the one-step ahead mean squared error (MSE) for each model selection technique.  $n$  is the number of candidate variables whereas  $q$  is the number of relevant regressors.

$q \setminus n$	$T=50$		$T=100$		$T=300$		$T=500$	
	100	300	100	300	100	300	100	300

### 3.2. Comparing the methodologies

To facilitate the comparison between the model selection techniques, this section presents the “winner” and the “2<sup>nd</sup> winner” methodology in each statistics present in Section 3.1. The results were obtained comparing the values in Table 1, Tables 2-5

and Table 6, for the *Autometrics* (Liberal), *Autometrics* (Conservative), LASSO and adaLASSO. The tables present the “winner” methodology for each simulated scenario, i.e. for each value of  $n$ ,  $T$  (in the lines) and  $q$  (in the columns).

Table 8 presents the “winners” for parameters estimation, i.e. the methodology that provides the lowest average bias and average MSE for the estimator, using the values in Table 1, for each scenario. Both for bias and MSE, the *Autometrics* (Conservative) is the “winner” for almost all scenarios. To have a better visualization of the difference between methodologies, we plot in Figure 5 and Figure 6 the values in Table 1 (Bias and MSE, respectively), for  $n=100$  and  $n=300$ . Each surface represents a model selection technique, according to the colors legend. The plot axes are the sample size ( $T$ ) and the number of relevant variables ( $q$ ). Figures 5 and 6 illustrate the results in Table 8, and show that both bias and MSE present a large increase when  $T$  is small and  $q$  is large, especially for LASSO and adaLASSO.

Table 9 and Table 10 give the “winners” for the selection statistics present in Tables 2-5. Table 9 provides the “winners” and “2<sup>nd</sup> winners” for Panel (a), and Panel (d), (e) and (f) (the three Panels present the same “winners”) statistics in Tables 2-5, i.e., the methodology that maximizes Panel (a) and Panel (d) statistics, and minimizes Panel (e) and Panel (f) statistics (using the criterion that the more parsimonious the model selected, the better). Again, *Autometrics* (Conservative) is the “winner” for almost all scenarios.

The four methodologies present similar results for the statistics in Panel (b) and (c) in Tables 2-5, Table 10 provides all winners for each scenario for Panel (b) and (c) (both Panels present the same “winners”). In other words, for one scenario, more than one methodology can present the best result. Therefore, we are analyzing the “worse” methodology (or methodologies) for each simulated scenario. As noted in Tables 2-5, *Autometrics* (Liberal and Conservative) presents a better performance in including the true model only when  $T=50$ .

Figures 7-12 provide the plot for all Panels statistics in Tables 2-5. Figures 7, 10, 11 and 12 clearly indicate a superior performance of the *Autometrics* (Conservative) in the statistics of Panel (a), (d), (e) and (f) in Table 9. Figures 8 and 9 illustrate the results of Table 10 for the statistics in Panel (b) and (c).

Table 11 gives the “winner” for the forecasting, i.e. the methodology that presents the lowest MSE for the one-step ahead out-of-sample forecast, as presented in Table 6, for each scenario. *Autometrics* (Conservative) is the “winner” for almost

all simulated scenarios, and the adaLASSO is the “2<sup>nd</sup> winner” in most of scenarios. Figure 13 plots the MSE of the forecast out-of-sample. It is clear that all methodologies has similar performance out-of-sample, excluding the scenario where  $T=50$  and  $q=15$  or  $20$ , in which LASSO and adaLASSO present a much larger MSE.

TABLE 8. PARAMETER ESTIMATES: WINNER

The table reports for each scenario, the winner and the 2<sup>nd</sup> winner for the average absolute bias and the average mean squared error (MSE), over all parameter estimates and Monte Carlo simulations.  $n$  is the number of candidate variables,  $q$  is the number of relevant regressors and  $T$  is the sample size.

$n$	$T \backslash q$	5	10	15	20	5	10	15	20

#### 4. Application - GDP forecasting

An important problem in economics is the prediction of the future evolution of GDP growth. Forecasts are typically produced either from economic theory based models or from simple linear time series models. A time series model can provide a reasonable benchmark to evaluate the value added of economic theory relative to the pure explanatory power of the past behavior of the variable. The problem faced by economists is that the economic growth theory is not explicit about what variables matter for growth. This difficulty has led empirical economists to follow theory loosely and simply “try” various sets of variables relating the potentially important determinants of growth. However, the regressions combining various variables showed that inclusion of one variable could affect the significance of the others. Since

we do not know *a priori* the “true” variables that should be included, we are left with the question: what are the variables that are really correlated with growth?

An initial answer to this question was given by Levine and Renelt (1992). They used cross-country regressions to identify “robust” empirical relations in the economic growth literature. Moreover, Sala-I-Martin, X. (1997) combined 62 variables in two millions cross-sectional regressions, and succeed to identify some variables strongly related to growth.

In this section, our aim is to use model selection techniques to identify significant variables in the forecast of growth, using time series regression. We are going to compare the results using *Autometrics* (Liberal and Conservative), LASSO, adaLASSO, and some benchmark models.

#### 4.1. The model

In order to compare the different model selection techniques in terms of predictive power (forecast out-of-sample), we consider the quarterly US GDP forecasting one-step ahead. We also study the identification of relevant variables in the linear regression, in next section.

The recent empirical literature on economic growth has identified a substantial number of variables that are partially correlated with the rate of economic growth. The basic methodology, presented in the literature for time series forecast of the GDP, consists of running linear regression with explanatory variables, which vary across researchers and papers.

Our main goal is selecting the variables really correlated with the growth, using the techniques compared here, and performing the forecast out-of-sample one-step ahead using the model selected. For that, we define the general unrestricted model (GUM) in equation (9).

$$y_t = \sum_{i=1}^4 \beta_{0,i} y_{t-i} + \sum_{k=1}^n \sum_{i=1}^I \beta_{k,i} x_{k,t-i} + \varepsilon_t, \quad \varepsilon_t \sim IN[0, \sigma^2] \quad (9)$$

where  $x_{k,t-i}$  is the  $i^{th}$  lag of the  $k^{th}$  explanatory variable, and  $I = 1$  or  $4$ .

## 4.2. The data

The dataset was obtained from the Federal Reserve Bank of Philadelphia and is part of the database called “Real-Time Data Set for Macroeconomists”, which consists of vintages of major macroeconomic variables<sup>6</sup>. For the present work, we used only the vintage available at the third quarter of 2011, which contains data from the first quarter of 1959 and ends in the second quarter of 2011, say 210 observations. The dependent variable corresponds to the US real GDP. We consider a total of 64 explanatory variables, related in Table 12.

All variables have been pretested for unit-roots and first-differenced whenever necessary. After taking the first difference and the 4 lags of the variables, we got 205 observations. And the sample period covers the second quarter of 1960 to the second quarter of 2011. We use 80% of the data for the specification and estimation of the models in-sample, and the final 20% for the forecast out-of-sample according to Table 13.

Table 12

### *Data Description*

Name	Series
<b>ROUTPUT</b>	Real GNP/GDP – (dependent variable)
<b>RCON</b>	Real Personal Consumption Expenditures: Total
<b>RCONG</b>	Real Personal Consumption Expenditures: Goods
<b>RCONND</b>	Real Personal Consumption Expenditures: Nondurable Goods
<b>RCOND</b>	Real Personal Consumption Expenditures: Durable Goods
<b>RCONS</b>	Real Personal Consumption Expenditures: Services
<b>RCONSHH</b>	Real Household Consumption Expenditures for Services
<b>RCONSNP</b>	Real Final Consumption Expenditures of NPISH
<b>RINVBF</b>	Real Gross Private Domestic Investment: Nonresidential
<b>RINVRESID</b>	Real Gross Private Domestic Investment: Residential
<b>RINVCHI</b>	Real Gross Private Domestic Investment: Change in Private Inventories
<b>REX</b>	Real Exports of Goods and Services

<sup>6</sup> “A real-time data set shows the observations for a variable as those observations were revised over time. The Philadelphia Fed’s real-time data set records snapshots, or vintages, of the data as they existed at various points in time in the past, before the data were fully revised. The vintage is an important concept in a real-time data set: It refers to the date on which the data were available to the public”. For more details see: [http://www.phil.frb.org/research-and-data/real-time-center/real-time-data/data-files/documentation/gen\\_doc\\_NIPA.pdf](http://www.phil.frb.org/research-and-data/real-time-center/real-time-data/data-files/documentation/gen_doc_NIPA.pdf)

<b>RIMP</b>	Real Imports of Goods and Services
<b>RG</b>	Real Government and Gross Investment: Total
<b>RGF</b>	Real Government and Gross Investment: Federal
<b>RGSL</b>	Real Government and Gross Investment: State and Local
<b>NOOUTPUT</b>	Nominal GNP/GDP
<b>NCON</b>	Nominal Personal Consumption Expenditures
<b>NCONG</b>	Nominal Personal Consumption Expenditures: Goods
<b>NCONSHH</b>	Nominal Household Consumption Expenditures for Services
<b>NCONSNP</b>	Nominal Household Consumption Expenditures of NPISH
<b>NCONHH</b>	Nominal Household Consumption Expenditures
<b>WSD</b>	Wage and Salary Disbursements
<b>OLI</b>	Other Labor Income
<b>PROPI</b>	Proprietors' Income
<b>RENTI</b>	Rental Income of Persons
<b>DIV</b>	Dividends
<b>PINTI</b>	Personal Interest Income
<b>TRANR</b>	Transfer Payments
<b>SSCONTRIB</b>	Personal Contributions for Social Insurance
<b>NPI</b>	Nominal Personal Income
<b>PTAX</b>	Personal Tax and Nontax Payments
<b>NDPI</b>	Nominal Disposable Personal Income
<b>PINTPAID</b>	Interest Paid by Consumers
<b>TRANPF</b>	Personal Transfer Payments to Foreigners
<b>NPSAV</b>	Nominal Personal Saving
<b>RATESAVE</b>	Personal Saving Rate, Constructed
<b>NCPROFAT</b>	Nominal Corporate Profits After Tax Without IVA/CCAdj
<b>NCPROFATW</b>	Nominal Corporate Profits After Tax With IVA/CCAdj
<b>PCON</b>	Price Index for Personal Consumption Expenditures, Constructed
<b>PCONG</b>	Price Index for Personal Consumption Expenditures: Goods
<b>PCONSHH</b>	Price Index for Household Consumption Expenditures for Services
<b>PCONSNP</b>	Price Index for Final Consumption Expenditures of NPISH
<b>PCONHH</b>	Price Index for Household Consumption Expenditures
<b>PCONX</b>	Core Price Index for Personal Consumption Expenditures
<b>PIMP</b>	Price Index for Imports of Goods and Services
<b>POP</b>	Civilian Noninstitutional Population, 16+
<b>LFC</b>	Civilian Labor Force, 16+
<b>LFPART</b>	Civilian Participation Rate, 16+, Constructed
<b>RUC</b>	Unemployment Rate
<b>EMPLOY</b>	Thousands of employees, seasonally adjusted
<b>HG</b>	Indexes of Aggregate Weekly Hours: Goods-Producing
<b>OPH</b>	Output Per Hour: Business Sector
<b>ULC</b>	Unit Labor Costs: Business Sector
<b>IPT</b>	Industrial Production Index: Total
<b>IPM</b>	Industrial Production Index: Manufacturing
<b>CUM</b>	Capacity Utilization Rate: Manufacturing
<b>HSTARTS</b>	Housing Starts
<b>BASEBASA</b>	Monetary Base
<b>CPI</b>	Consumer Price Index
<b>M1</b>	M1 Money Stock

<b>M2</b>	M2 Money Stock
<b>TRBASA</b>	Total Reserves
NRRBASA	Nonborrowed Reserves
NBRECBASE	Nonborrowed Reserves Plus Extended Credit

TABLE 13. GDP FORECASTING: TRAINING AND TEST PERIOD

The table reports, the number of observation, the quarter of the beginning and the quarter of the end of each period in the linear regression.

Period Description	Number of Observations	Beginning	End
Total	205	1960 q2	2011 q2
Training (in-sample)	164	1960 q2	2001 q1
Test set (out-of-sample)	41	2001 q2	2011 q2

Table 12 contains some highly correlated variables. Some are simply linear combination of others. In order to test the model selection techniques in the presence of collinearity, we used two different sets of explanatory variables. In other words, we compared the methodologies using two different GUMs. In the first GUM we included the 64 explanatory variables and their lags, and in the second GUM we included only the variables that appear in bold in Table 12, 46 variables, taking out highly correlated variables.

In order to compare the methodologies in both cases, where the number of candidate variables exceeds the number of observations ( $n > T$ ), and where the number of candidate variables does not exceeds the sample size ( $n < T$ ), we used two different sets of lags in each GUM. The first set of regressors (GUM\_1) is composed by the first 4 lags of the GDP ( $y_{t-1}, \dots, y_{t-4}$ ), and the first lag of the explanatory variables ( $X_{t-1}$ ). The second set of variables (GUM\_2) is composed by the first 4 lags of the GDP ( $y_{t-1}, \dots, y_{t-4}$ ), and the first 4 lags of the explanatory variables ( $X_{t-1}, \dots, X_{t-4}$ ).

### 4.3. Results

We compare the *Autometrics* (Liberal and Conservative), LASSO, and adaLASSO, with three different benchmark alternatives: a linear regression with all the regressors included (GUM), a simple first-order AR model (AR(1)), and a fourth-order AR model (AR(4)). The results are presented in Table 14.

In the case where we consider all 64 variables (Panel 1), we observe that both LASSO and adaLASSO models are far superior than the benchmarks and *Autometrics*

models in the results out-of-sample. In this case, with the presence of highly correlated candidate variables, *Autometrics* models present negative out-of-sample R2, except in the case of Aut-C\_1, where  $R2_{out} = 0.169$ . However, in the case where we only considered 46 variables (Panel 2), the *Autometrics* (Liberal) performs similar to LASSO and adaLASSO models, when  $n > T$  (Aut-L\_2). Table 14 shows that *Autometrics* is very sensible to changes in the set of candidate variables and to the collinearity of the regressors, while LASSO and adaLASSO models are more stable.

We notice also that the model with all the regressors (GUM) presents the worse out-of-sample performance, and, as expected, the largest in-sample R2, due to the high number of parameters, in all cases. The GUM\_2, in Panel 1 and Panel 2, present lower BIC than model selection techniques, due to over parameterization ( $n > T$ ). GUM models present negative out-of-sample R2 in every case. Negative values of R2 mean that it is worse using the model than simply using the historical mean of the dependent variable as forecast.

Table 14 shows that the best model out-of-sample within *Autometrics* (Liberal and Conservative), LASSO and adaLASSO (largest out-of-sample R2, and lowest RMSE), is the worse model in-sample (largest BIC) in most of the cases. This fact gives an indication that using the information criteria (in-sample) to select models may not be a good strategy, as we can notice in the case of models Aut-L\_2 and Aut-C\_2 in Panel 1, where they present the lowest BIC of the four techniques compared and the lowest out-of-sample R2 and largest out-of-sample RMSE. Finally, in the GDP forecasting application, we conclude that the best model selection technique is the adaLASSO, when  $n < T$ , and the LASSO, when  $n > T$ .

TABLE 14. GDP FORECASTING: DESCRIPTIVE STATISTICS

The table reports, for each different set of explanatory variables and different set of lags, the in-sample and out-of-sample R2, the out-of-sample root mean squared error (RMSE), the Bayesian Information Criterion (BIC), and the number of parameters, for each model selection technique, and benchmark models.

Model	R2_in	R2_out	RMSE_out	BIC	num par

### 4.3.1. Study of the relevant variables

In this section we present the relevant variables in the models selected by the model selection techniques. Table 15 and Table 16 show the variables per model, the total number of models in which each variable appears, the total number of parameters of each model, and the variables description, for the experiment considering 64 and 46 explanatory variables, respectively. We consider here that the models presenting negative out-of-sample R2 were not able to select a satisfactory model for the US GDP, therefore we don't consider them in this section.

Table 15 contains the variables present in models LASSO\_1, adaLASSO\_1, LASSO\_2, adaLASSO\_2 and Aut-C\_1, considering the GUM with 64 explanatory variables. LASSO\_1, adaLASSO\_1 and Aut-C\_1 were selected from a set of 68

candidate variables (GUM\_1), while LASSO\_2 and adaLASSO\_2 were selected from a set of 260 candidate variables (GUM\_2), as presented in Panel 1 of Table 14.

Analyzing the relevant variables in Table 15, we notice that three regressors are present in all LASSO and adaLASSO models: Real Household Consumption Expenditures for Services; Real Imports of Goods and Services; and Real Gross Private Domestic Investment: Residential. This can be an indication that these three economic variables can explain GDP better than the other candidate variables.

TABLE 15. GDP FORECASTING: RELEVANT VARIABLES - 64 EXPLANATORY VARIABLES

The table shows the relevant variables (regressors) per model (only models with positive out-of-sample R2 in Panel 1 of Table 14: LASSO\_1, adaLASSO\_1, LASSO\_2, adaLASSO\_2 and Aut-C\_1), the number of models in which each variable appears, the number of parameters of each model, and the variables description.

Considering 64 explanatory variables							
Variable	LASSO_1	adaLASSO_1	LASSO_2	adaLASSO_2	Aut-C_1	num models	Description
EMPLOY (t-1)					X	1	Thousands of employees, seasonally adjusted
HSTARTS (t-1)				X		1	Housing Starts
NCPROFATW (t-1)					X	1	Nominal Corporate Profits After Tax With IVA/CCAdj
NPSAV (t-1)					X	1	Nominal Personal Saving
PROPI (t-2)			X	X		2	Proprietors' Income
RCOND (t-1)		X		X		2	Real Personal Consumption Expenditures: Durable Goods
RCONND (t-2)			X	X		2	Real Personal Consumption Expenditures: Nondurable Goods
RCONS (t-1)		X		X	X	3	Real Personal Consumption Expenditures: Services
RCONSHH (t-1)	X	X	X	X		4	Real Household Consumption Expenditures for Services
RIMP (t-1)	X	X	X	X		4	Real Imports of Goods and Services
RINVRESID (t-1)	X	X	X	X	X	5	Real Gross Private Domestic Investment: Residential
ROUTPUT (t-1)					X	1	Real GNP/GDP
TRANPF (t-1)					X	1	Personal Transfer Payments to Foreigners
ULC (t-2)			X	X		2	Unit Labor Costs: Business Sector
<b>num par</b>	<b>3</b>	<b>5</b>	<b>6</b>	<b>9</b>	<b>7</b>		

Table 16 contains the variables present in models LASSO\_1, adaLASSO\_1, LASSO\_2, adaLASSO\_2, Aut-L/C\_1, and Aut-C\_2, considering the GUM with 46 explanatory variables. Aut-L/C\_1 represents Aut-L\_1 and Aut-C\_1 as both methodologies resulted in the same selected model. LASSO\_1, adaLASSO\_1 and Aut-L/C\_1 were selected from a set of 50 candidate variables (GUM\_1), while LASSO\_2, adaLASSO\_2 and Aut-L\_2 were selected from a set of 188 candidate variables (GUM\_2), as presented in Panel 2 of Table 14.

In Table 16, two regressors are present in all six models: Real Personal Consumption Expenditures: Services; and Real Gross Private Domestic Investment: Residential. And one regressor is present in all LASSO and adaLASSO models: Real Imports of Goods and Services. Once again this can be an indication that these three economic variables can explain GDP better than the others candidate variables.

Table 15 and 16 show that LASSO\_2 and adaLASSO\_2, present the same regressors that LASSO\_1 and adaLASSO\_1, and some more. In other words,

LASSO\_1 is nested in LASSO\_2 and adaLASSO\_1 is nested in adaLASSO\_2. This indicates that there is some information about the GDP in the 3 lags that does not enter the GUM\_1, but enters the GUM\_2 ( $X_{t-2}, \dots, X_{t-4}$ ), even if out-of-sample R2 of LASSO\_2 and adaLASSO\_2 are lower.

TABLE 16. GDP FORECASTING: RELEVANT VARIABLES - 46 EXPLANATORY VARIABLES

The table shows the relevant variables (regressors) per model (only models with positive out-of-sample R2 in Panel 2 of Table 14: LASSO\_1, adaLASSO\_1, LASSO\_2, adaLASSO\_2, Aut-L/C\_1, and Aut-C\_2), the number of models in which each variable appears, the number of parameters of each model, and the variables description.

Considering 46 explanatory variables								
Variable	LASSO_1	adaLASSO_1	LASSO_2	adaLASSO_2	Aut-L/C_1	Aut-L_2	num models	Description
EMPLOY (t-1)					X	X	2	Thousands of employees, seasonally adjusted
EMPLOY (t-3)						X	1	Thousands of employees, seasonally adjusted
HG (t-1)						X	1	Indexes of Aggregate Weekly Hours: Goods-Producing
HSTARTS (t-1)				X			1	Housing Starts

## 5. Conclusion

In this paper we evaluated a comparison between model selection techniques. First we explain the *PcGets* and *Autometrics* methodology and algorithms, and the LASSO and adaLASSO techniques and estimators. For the comparison we evaluate a Monte Carlo simulation with a simple linear regression as DGP, and an application to US GDP forecasting. Two aspects of the performance were considered: the predictive power (forecast out-of-sample) and the performance in the selection of the correct model and estimation (in-sample). The case where the number of candidate variables exceeds the number of observation was considered as well.

In the simulation experiment, we compared the different model selection methodologies in different simulated scenarios, varying the sample size ( $T$ ), the number of relevant variables ( $q$ ) and the number of candidate variables ( $n$ ).

In a general way, we can conclude that when  $T$  is large and  $q$  is small, all

selection techniques present a similar performance, with *Autometrics* (Conservative) presenting a slight gain. However, in extreme cases with more candidate variables than observations ( $n > T$ ), and large values of number of relevant variables ( $q$ ), *Autometrics* (Conservative) can perform considerably better than the others, especially when compared to LASSO and adaLASSO. It is important to notice that the final models selected by the methodologies in this paper always present less regressors than observations, as expected in a linear regression. The regressions with more variables than observation only appear in the GUM models, before variable selection.

Results in Section 3 showed that adaLASSO estimator gets closer to the Oracle than the LASSO estimator, as expected. However, Section 3.1 and 3.2 suggested that LASSO and adaLASSO techniques present similar performance in the model selection and forecasting, in the simulation experiment.

Results in Section 4 showed that the models estimated by the LASSO and adaLASSO procedure delivered forecasts significantly superior than *Autometrics* and benchmark models, when applied to US GDP time series. Results also suggest that the selected models by the methodology outperform the general unrestricted models (GUM). This is an important result, as the methodologies compared in the paper are based on the assumption that only a few numbers of candidate variables are in fact relevant to explain the dynamics of the dependent variable. In this application, the forecasts results showed that the LASSO and adaLASSO procedures are more robust than *Autometrics* algorithm.

The simulation and application results differ in pointing out the “best” model selection technique. In the simulation, the *Autometrics* (Conservative) showed better results in a general way, while in the application to real data, the LASSO and adaLASSO outperformed the *Autometrics*. However, in the simulation experiments, the difference between the four techniques was quite small, while in the application, the results presented by LASSO and adaLASSO forecasts were a lot more satisfactory than the results presented by *Autometrics* (Liberal and Conservative) forecasts.

The results in Section 4.3 lead us to two important questions: The “best” model in-sample is the “best” model out-of-sample? Under a stationary environment the answer is yes, but, in real world, results can vary according to data and the sample split point, as showed in Hansen and Timmermann (2012). It is important to

wondering if in-sample criteria, as AIC or BIC, are really the best way of choosing models for forecasting. The second question is: Can *Autometrics* algorithm really handle collinearity as suggested in Hendry and Krolzig (2005)? As we could see in Panel 1 of Table 14, models estimated by *Autometrics* present unsatisfactory out-of-sample results when the candidate variables are correlated, while LASSO and adaLASSO manage to select models with satisfactory statistics, in terms of out-of-sample R2 and RMSE. These are important subjects for future research.
