- Virtual reconstruction of the cranium and mandible
- Facial approximation to account for injuries

Abstract

The invasion of Russia by the Napoleonic *Grande Armée* was a complete disaster. The French army was decimated during the retreat from Russia. Thousands of victims were buried in mass graves located near several cities during the retreat. One of these mass graves was discovered in in the center of Kaliningrad (formerly Königsberg), presently the most occidental oblast of the Russian Federation. Some skeletons revealed evidence of violence related traumatic injuries. Among them, the skeleton C2 belonged to a young male, who had

suffered a serious injury to the lower face. The state of post-traumatic remodeling indicated survival of about 2 months (between more than 6 weeks and less than 3 months).

The 3D reconstruction of the mandible and the maxilla contributed additional information about the injury, its cause and treatment. This permitted pre-traumatic reconstruction of the viscerocranium and mandible through the application of two new techniques: virtual osteotomy and virtual bone transplant from another individual and perform an approximation of the face (to recreate the soft tissues) of this unidentified soldier using AFA3D software. These results highlight the use of 3D methods in paleopathology and forensic anthropology to reconstruct traumatic facial injuries and the pre-traumatic facial appearance.

Introduction

In 1812, in response to Russia's withdrawal from the continental blockade of the United Kingdom and to liberate Poland, Napoleon I invaded Russia. This military campaign was a disaster and the *Grande Armée* was decimated. Napoleon was forced to retreat from Moscow which has been set on fire by its inhabitants. The French defeat at the Battle of Berezina (November 1812) brought an end to this disastrous campaign. However, the extremely cold Russian winter; infectious diseases, in particular typhus; and starvation killed more soldiers than did the battles against the Russian troops (de Beauchamp, 1825; Noël, 1895; Boudon, 2012). Hundred thousand victims were buried in mass graves that marked the passage of increasingly desperate troops (Signoli *et al*., 2004, 2008; Dutour *et al.,* 2014, 2015). Königsberg, capital city of Eastern Prussia, today known as Kaliningrad, Russian Federation, was one of the places where the survivors of the *Grand Armée* had a short rest in late December 1812 (Larrey, 1817; Noël, 1895).

In July-August 2006, salvage excavations due to construction were conducted in the center of Kaliningrad by a team form the Department of Salvage Archaeology (Institute of Archaeology, Russian Academy of Sciences) under the supervision of Alexander Khokhlov (Buzhilova et al., 2009). In addition to the discovery of fortifications of the old city of Königsberg, the capital of Eastern Prussia, twelve mass graves containing the remains of at least 600 individuals were discovered. The skeletons were associated with military buttons, remains of textiles, shakos, shoes, boots and coins that led to identification these remains as those of Napoleonic soldiers of the *Grande Armée*. This archeological and anthropological material was studied under the auspices of the CNRS French-Russian Laboratory (LIA K1812, CNRS-RAS / EPHE-Moscow State University).

The skeletal remains of soldiers revealed 103 instances of violence-related trauma, including fractures, weapon wounds and evidence of field surgery such as amputations (Dutour and Buzhilova, 2013). Among these cases, Individual 2 from Pit C (C2) exhibits a serious wound in the lower part of his face, which is the subject of this study. The 3D method of virtual reconstruction was employed in order to: (1) to understand the trauma etiology, (2) to virtually reconstruct the missing parts of the facial bones to restore the entire facial skeleton and (3) to provide a facial approximation.

Material and methods

In pit C, 26 skeletons were identified. All the individuals but two were young adult males. Their corpses had been buried directly in the ground, except one, which was buried in a wooden coffin (Buzhilova et al, 2009; Dutour & Buzhilova, 2013). There was no particular organization in the deposit of the skeletons, but in the lower layer, the coffin and some skeletons were placed along a North/South axis with the head oriented towards the North. In

the upper layer, the skeletons were positioned perpendicular to the coffin in a foot-to-foot position. There was no preferential burial position (figure 1). Skeleton C2, was identified as that of a young male (about 20-25 years old; following Buikstra and Ubelaker (1994) method), showing a serious wound in the lower part of his face (figure 2): this injury fractured the left side of the mandible, the maxillary bones and anterior teeth (Dutour and Buzhilova, 2013). Sex determination was based on the visual discriminant method of the *ossa coxae* (Bruzek 2002) and the probabilistic method developed by Coqueugniot *et al.* (2010) for estimating age-at-death, which combines sites and stages of epiphyseal fusion. A computer tomographic scan of the cranium and mandible was performed at the Department of Radiology of Moscow State University by one of us (A. V.) on a Philips Brilliance 64 device, using a 512 x 512 matrix, a slice thickness of 0.47mm, an exposure time of 780 ms, and a X-ray tube current of 128 mA. CT data were analyzed using TIVMI® software, developed by Dutailly *et al.* (2009). TIVMI® has demonstrated an accuracy comparable to other 3D reconstruction software (Guyomarc'h *et al*. 2012) as it uses the HMH algorithm (Spoor *et al*. 1993) extended to 3D.

The first step of this procedure produced a semi-automatic segmentation based on the different densities of skeletal tissues: cortical bone, trabecular bone, teeth and remodeled bone corresponding to callus formation. We named 'remodeling bone' this newly formed bone tissue (so-called callus) corresponding to a healing process still in progress at the time of death. It clearly differs on the CT-slices in its density and structure from the more mature bone. These segmented slices were then converted by TIVMI in a 3D model of the cranium and mandible as it appeared at its discovery. The precision of TIVMI was crucial to the successful completion of this step. The pre-traumatic state was reconstructed by using TIVMI® and Geomagic Studio® softwares. It required the removal of the actively remodeling bone and replacing fragments in their pre-traumatic anatomical positions. In some

highly fragmented areas, the process of bone remodeling affected cortical bone. The irregularities of cortical surface associated with displacement of bone splinters, were revealed only after the segmentation and 3D reconstruction. A virtual osteotomy was performed in order to remove these irregularities. The level of the osteotomy was determined by superimposing the affected side on a mirror image of the unaffected side, which served as a guide for removal of these irregularities.

The missing parts were recreated using two techniques: by symmetry when possible (mirror imaging, Gunz *et al.* 2009) or by using a reference individual (virtual bone transplant) when the anatomical region was missing from both sides of the facial skeleton. For the application of the latter technique, the CT scan of a 22-year-old French man was used. The data had been anonymized, with only the age and sex of the individual being known. Craniofacial CT-scans of this individual had been performed for medical reasons other than trauma or masticatory pathology. Facial approximation was performed using TIVMI® and the AFA3D plug-in. The software uses geometric morphometrics and statistical models to estimate facial soft tissue depth and facial shape. Seventy-eight bone landmarks were used to estimate 100 cutaneous landmarks. The software database consists of a reference sample composed of 500 CT-scan of adults (of which 265 are males) from several hospitals in France. Age, sex and body mass can be estimated (Guyomarc'h et al., 2014). Phenotypic details were added using the software Blender®. Eye color, hair and skin pigmentation were selected based on those representing the most common phenotypes noted in the military registers of the Napoleonic regiments (Degioanni, 2012). The uniform corresponds to one of the regiments identified in the pits due to the presence of military buttons.

Results

The male sex was confirmed and the age-at-death was estimated with a probability of 98% as belonging to the 24-27 year-old age category. Therefore, this result places this individual's birth between 1785 and 1788- that is to say, before the French Revolution.

Paleotraumatological description

The mandible consists of two main fragments: the right ramus and a large part of the symphysial region attached to the left side of the bone. Most of the right mandibular corpus from the first premolar to the ramus is missing. A fracture callus can be seen in the inferior and lateral parts of the right ramus. The CT-scan images permitted identification of five osseous fragments by separating them from the bone callus. Three of these fragments from the inferior region were not in their anatomic position, being displaced laterally or medially. In this area, the remodeling bone is strongly developed, completely surrounding these bone fragments. The outline of this callus is not perfectly smooth. The segmentation of CT-scan images also confirmed that the entire lateral side of the ramus was affected by remodeling processes, even the superior part, far from the lesion.

A fracture between the left side and the symphysis region can be seen in the main fragment. The 3D images revealed a third fragment, surrounded by remodeling bone on the lingual side of the symphysial region. The bone healing process seems much more advanced around this small fragment than around the main fracture on the left side of the mandible. The remodeling processes affect mainly the trabecular bone in this region (Figure 3).

All teeth, except the three left molars, are missing. The dental alveoli do not show any evidence of bone remodeling. A part of the right maxilla and the anterior teeth (incisors, canines and right premolars) are missing. The trauma impacted the maxillary body, the alveolar and palatine processes. The frontal and the zygomatic processes remain relatively unaffected. The segmentation of this region did not permit identification of any fragments

within the new bone formation. The first left premolar is broken, with an oblique anteroposterior and downward fracture; the root is still visible in the dental alveolus. The second left premolar was initially present but fell out during the lab study.

Re-examination of the field photographs show that most of this missing maxillary fragment was originally in place during excavation (Figure 1). This bone fragment was probably misallocated when skeletons were rapidly removed due to time pressure imposed by the real estate developer in the context of a rescue excavation (Dutour and Buzhilova, 2013). The fragment was not present among the bags of remains during the lab study performed at the Museum of Kaliningrad in September 2006 (Dutour, pers. com.).

The remodeling process in the remaining right maxilla is poorly developed, and may correspond to a healing without a great gap (Marsell and Einhorn, 2011) between the traumatic event and death. The nasal bones are not present; the breakage in this region corresponds to recent postmortem break (Lovell, 1997; Marin-Monfort et al., 2017). The nasal aperture is deviated to the right, while the perpendicular plate of the ethmoid is deviated to the left. No others parts of the upper face seem to be affected by traumatic or taphonomic processes. No other particular marks are visible on the cranium and no remains of weapons, such as lead bullets or blade fragments, are present.

Reconstruction of the pre-traumatic state

The fragments of the symphysis and left side of the mandible were correctly positioned and re-assembled after the removal of the newly formed bone of the callus. A virtual osteotomy was performed on the inferior part of the right ramus (inferior to the mandibular foramen). Indeed, this part of the bone was much remodeled and distorted due to the poor re-positioning of the fragments following the traumatic episode. The right corpus was recreated by mirror-imaging using the preserved left side of the mandible (Figure 4). The reconstruction of the

maxilla was not possible using mirror imaging. Indeed, no preserved part could be used to recreate the missing ones. To overcome this obstacle, clinical CT data from a young French man of similar maxillary size and robustness and comparable age (22 years old) was virtually transplanted into the portion of his maxilla corresponding to missing part of soldier's face (Figure 5). These 3D reconstruction and restoration processes of the mandible and maxilla allowed us to obtain a virtual complete skull (Figure 6). Therefore, it has been possible to perform an approximation of the individual's face using the AFA3D software. This provides a neutral facial model (Figure 7A). Upon completion of this procedure, the resulting facial approximation was further enhanced with the addition of realistic pigmentation and texture details using Blender software (Figure 7B).

Discussion

The facial lesions of this individual affecting both the mandibular and maxillary bones correspond to severe facial trauma. The presence of sharp force trauma excludes a simple accidental cause. The victim was probably wounded during a fight against Russian troops. Violence-related traumatic injuries can be due to various weapons, including firearms (rifles and pistols), cannons, and edged weapons such as sabers. These lesions do not correspond to a firearm injury as no metallic artefacts, such as lead shot, were identified (Coqueugniot et al., 2015).

Therefore, the most probable weapon that produces this type of trauma is the heavy saber used by cavalry of the period. The maxillary fracture detached bone without any fragmentation, contrary to the mandible which was broken in several pieces. Thus, the maxilla was the area of intial impact, cutting off the anterior part of the maxillary process just inferior to the nasal aperture. Secondarily, the loss of velocity and energy caused by striking the

maxilla produced a major fracture of the right mandibular corpus. The fracture on the left side of the mandible may correspond to a balancing fracture resulting from the violent blow (Lovell, 1997). The force of the blow would be increased by the speed at which two mounted soldiers would clash. Bilateral extension of the articular surface is observed on the anterior surface of the femoral neck of this individual, a feature that is observed among 25% of the femora in this series (Dutour and Buzhilova, 2013), and that has been proposed as a skeletal indicator of horse-riding by some authors (Palfi, 1992; Molleson and Blondiaux, 1994; Palfi and Dutour, 1996, Baillif-Ducros et al, 2012; McGrath, 2015), even if this interpretation was questioned by other scholars (Radi et al, 2013).

It is difficult to determine the hand preference of the assailant. As the left side of the victim is affected, one possible scenario would be that the wound was received in a face-to-face confrontation with a left-handed opponent. However, the trajectory of the blow, from superior to inferior and slightly posteriorly, would better correspond with a blow delivered by a right-handed assailant who was on the left side of the victim. In this case, the lesion would correspond to a saber blow of the "*taille*", the blade of the sword. At this time in history, the "*estoc*" (with the tip of the sword) was the recommended part of the sword to wound an enemy combatant (de Brack, 1876). The "*taille*" causing extensive but superficial cuts, contrary to the "*estoc*" which causes smaller but deeper wounds but penetrates to reach vital organs. This kind of facial saber blow has been reported during the Russian campaign (Larrey, 1812; Noël, 1895).

The saber hypothesis is supported by the general appearance of the lesion and by the fracture angle on the left maxillary premolar, the same as that observed on the mandible. Soft tissues served as flaps that kept bone fragments in place. A very similar case of a facial wound caused by a saber occurred during the Russian Campaign, as described by Dominique Larrey, French surgeon in chief of the Grande Armée (Larrey, 1817). The patient, a Russian colonel,

saber-wounded during conflict with a French cavalryman, presented with a maxillary fracture, dental loss and severe soft tissue lesions of the nose and mouth: "Then I detached the portion of the palatal vault that held to the flap [of soft tissue]. It consisted of the anterior half of the upper alveolar arch. It had been separated from the rest of the jaw, on one side, between the canine and the first premolar, and, on the other, between the first two molars"[1].

To remedy this damage, Larrey recommended a precise procedure he had experimented several times with success: extraction of all the small bone fragments, mandibular fracture immobilization by means of external fixation (dental braces) and reconstruction of soft tissues by suture stitches (Larrey, 1812, 1817; Ferret-Dussart, 2004).

Remodeling processes observed on the maxilla and mandible show that this wound was severe but not immediately lethal. The firm attachment of the callus to the cortex, the relative smoothing of its outline and the incompleteness of the healing indicates that the victim survived between 6 weeks and 3 months after the trauma according to a method of determination of post-traumatic time interval (De Boer et al., 2015). Therefore it is most probable that the victim has been taken into care in one of the French military hospitals of Königsberg (Larrey, 1817; Noel, 1895), and treated according to the Larrey's surgical procedure. It should be noted that pits were located close to one of the French military hospitals of Königsberg (Buzhilova et al, 2009). This wounded soldier was on the way to recovery when he died, possibly from a co-morbid cause.

Epidemic outbreaks of typhus (*Rickettsia prowazecki*) and trench fever (*Bartonella quintana*) occurred in Königsberg in late 1812-early 1813 (Ozanam, 1835). Molecular biology

---

[11] « *Je détachai ensuite la portion de la voûte palatine qui tenait au lambeau. Elle se composait de la moitié antérieure de l'arcade alvéolaire supérieure. Elle avait été séparée du reste de la mâchoire, d'un côté, entre la canine et la première prémolaire, et, de l'autre, entre les deux premières molaires* » (Larrey, 1817)

has confirmed the presence of these two diseases in Vilnius (Raoult et al. 2006), a city located along the road to Königsberg. The poor physiological state due to having sustained a severe wound and consequent eating difficulties of this wounded combatant in the exhausting retreat and the extremely cold temperature may have been significant aggravating factors in his demise.

Conclusions

The virtual study of a traumatic injury using computed-tomodensitometry furthers understanding of a bone lesion, its causes and consequences. Study of CT-scan slices makes it possible to better observe the different tissues and thus better understand the blow. Moreover permits estimation of the post-traumatic survival time. As a complement to 2D analysis, this study demonstrates the value of 3D reconstruction of the mandible and the maxilla through the application of two original techniques: virtual osteotomy and virtual bone transplant. They permit reconstruction of the pre-traumatic state of the cranium and mandible. These two, easy to apply techniques differ from those commonly used in paleoanthropology (Gunz *et al*., 2009) but accurately approximate facial features. More than two centuries after his death, this facial reconstruction brings this unknown soldier's face back to the present.
