MIGRATORY EQUILIBRIA WITH INVESTED REMITTANCES

Claire Naiditch* and Radu Vranceanu†

April 2009

Abstract
This paper analyzes international migrations when migrants invest part of their income in their origin country. This investment contributes to increase capital intensity and wages in the origin country, thus reducing the scope for migrating. We show that a non-total migratory equilibrium can exist if the foreign wage is not too high, and/or migratory and transfer costs are not too low. Exogenous shocks, such as an increase in the foreign wage, lead to an increase in optimal remittances per migrant, and a higher wage in the origin country. Yet the net effect on the equilibrium number of migrants is positive. Hence, in equilibrium, optimal remittances and number of migrants are positively related. We use data from twenty five countries from Eastern Europe and Central Asia in 2000 in order to test for this implication of our model. OLS and bootstrap estimates put forward a positive elasticity of the number of migrants with respect to remittances per migrant. Policy implications follow.

Mots-clef: Migration, Remittances, Investment motive, Migratory Policy.

1 Introduction

International migration is one of the most important factors affecting economic interaction between developed and developing countries in the 21st century. In 2005, nearly 191 million people, representing 3% of the world population, live and work in a country different from the one where they were born or where they own citizenship. Among these migrants, we are particularly interested in migrants moving for economic reasons. In general, neoclassical economics explains these migrations as the result of an elementary cost/benefit analysis: individuals decide to migrate if the net discounted gain from migration is positive; the most important driving force is thus the wage differential between the origin and the destination country. More recently, the new economics of labor migration submitted the idea according to which migration is the normal response of individuals to various market deficiencies in developing countries and might not be driven only by the wage differential (Stark, 1991). In this context, individuals can choose to migrate in order to overcome failures of labor, credit or insurance markets.

Connected to economic migration are the ever growing flows of resources transferred by migrants towards their origin countries, the so-called remittances. Substantial empirical evidence has shown that remittances have a significant impact on the developing world. Nowadays, they constitute the second largest source of currencies for these countries, slightly behind foreign direct investments but before official development aid. In 2007, they amounted to more than 355 billion US$ of which 265 billion was directed towards developing countries.¹

Migrants can remit to their families and communities in their origin country for several reasons. Rapoport and Docquier (2006) list a series of motives than could explain the existence of remittances: altruism, exchange (purchase of various types of services, repayments of loans...), strategic motive (positive selection among migrants, signaling), insurance (risks diversification) and investment. Specialists' consensus is that in general a combination of all these motives is the driver of remittances in real life. However, since it is difficult to mix in the same model several motives, in general economists focus on one of them and study in depth its implications. For

instance, in models where insurance or altruism is the main motive, recipient households should modify their labor supply (Azam and Gubert, 2005; Chami et al., 2005; Naiditch and Vranceanu, 2009). If investment is the main motive, the impact on labor supply should be smaller, but labor demand might be impacted.

This paper analyses the existence and properties of migratory equilibria in the case where a significant share of the remittances sent back home by migrants are invested in capital formation. Several recent empirical studies have brought support to the assumption according to which investment is one of the main motivations to remit. Ratha (2003) argues that remittances are more and more often invested in capital formation, especially in low-income countries. He also points out that the amount and the volatility of the flow of remittances rose much more in the nineties, once developing countries had removed the barriers to international movements of capital. In his view, this brings additional support to the investment assumption. Lucas (1985) estimated that in five sub-Saharan African countries, emigration (towards South-African mines) had, in the short run, reduced work supply and harvests but that, in the long run, it permitted to improve agricultural productivity and to accumulate cattle, mainly due to the investment of remittances. Woodruff and Zenteno (2007) estimate that remittances coming from the United States represent close to $1/5^{th}$ of investments in urban micro-enterprises in Mexico. Likewise, the majority of Egyptian migrants returning to their origin country at the end of the 1980s started their own firms using repatriated savings from abroad (McCormick and Wahba, 2004). Comparisons between countries prove that remittances are affected by the investment climate in recipient countries in the same manner as capital flows, though to a much lesser degree. Between 1996 and 2000, for example, remitted amounts averaged 0.5% of GDP in countries with a corruption index (as measured by the index of the International Corruption Research Group) higher than the median level, compared to 1.9% in countries with a corruption index lower than the median level. Countries that were more open (in terms of their trade/GDP ratio) or more financially developed (M2/GDP) also received larger remittances (Ratha, 2003). In Eastern Europe, Leon-Ledesma and Piracha (2004) showed that remittances have a positive impact on productivity and employment, both directly and indirectly through their effect on capital formation.
Other authors have studied migratory equilibria in a framework not very different from ours, but did not considered the possibility that migrants’ remittances can drive up the stock of capital in the origin country. For instance, Galor (1986) worked out a two-country model with overlapping generations; he shows that if natives of each country are homogeneous, the whole population of the developing country will permanently emigrate in the long run, because permanent migration cannot induce a wage raise in the origin country strong enough to make migration a dominated strategy. Galor’s result depends on his assumption that all productive factors are perfectly mobile between countries: if one factor was fixed, labor productivity in the developing country would increase much more with migration (Karayalcin, 1994). Moreover, in Galor’s model, permanent migration of individuals implies permanent migration of capital, since each worker represents a potential source of capital for the country where he lives, given his savings. This implicit assumption holds no more if migrants can invest remittances in the origin country. Djajic and Milbourne (1988) also study migratory equilibria but in the case of temporary migration, with a predetermined stock of capital. Carrington, Detragiache and Vishwanath (1996) study migration in a dynamic model where migratory costs decrease with the number of migrants. They then show that even if migration depends on the differential between wages, migratory flows can increase when this differential decreases (because costs decline), and they lay down conditions for a steady migratory equilibrium. In their model too, the stock of capital is given.

A few recent papers study the potential impact of remittances on migration, but not specifically in the case of invested remittances. For instance, some scholars suggest that remittances could have a negative impact on migration. In an elementary framework, remittances contribute to the income of left home family members; then, if large enough, they can discourage additional household members to migrate (van Dalen et al., 2005). Stark (1995) works out an imperfect information model, with high and low productivity migrants, whose productivities cannot be observed directly by the would-be employers in the rich country. Hence the highly productive migrants would send remittances home to the low productivity workers in order to prompt them to stay. Some other researchers suggest that the link between remittances and migration could be positive. This positive relationship can be obtained in a loan repayment model, where the
migrant committed himself to reimburse his family who paid for the up-front cost of migration, and to help other family members to migrate in the future; this rationale seems to be supported by an empirical study on Pakistani data (Ilahi and Jafarey, 1999). Finally, remittances could be interpreted as signals of financial attractiveness of destination countries and thus, trigger chain migration; this effect seems to be supported by two empirical studies, one conducted with data on Egypt, Turkey and Morocco for households with family members living abroad (van Dalen et al., 2005), and the other using longitudinal data from Bosnia and Herzegovina (Dimova and Wolff, 2009). In a different set-up, Stark and Wang (2002) analyze a problem where skilled and unskilled migrants are partially complementary inputs; hence skilled workers’ wages increase with the number of unskilled workers. Then skilled migrants may decide to subsidize unskilled workers’ wage, in order to attract them to the host country. In the same line of reasoning, skilled workers might send remittances to unskilled workers to help them pay for the migratory cost.

In this paper, we build a very simple model aiming at characterizing migratory equilibria, based on the elementary neo-classical trade-off between discounted gain if migrating and discounted gain if staying. We emphasize the relationship between invested remittances, migration and wages in the origin country. To keep the analysis as simple as possible, we abstract from the consequences of migration on the destination country; in particular, we assume that the migrant’s wage rate in the host country does not depend on the number of migrants, and that all migrants can find a job.$^2$

Such a set up is most suitable to analyze migration from relatively small low-income countries to large developed countries. Migrants are consistently selfish: they migrate in order to obtain a higher intertemporal satisfaction, and they remit and invest their savings in the origin country for the same reason. Probably migrants can invest their savings in other countries, including in the host country. To keep the analysis as simple as possible, we assume that they present some form of "origin country bias"; this is more plausible in the case of temporary migrants, who plan to "move close" to their investment in the future.$^3$

---

$^2$ There is no consensus in the literature (mostly empirical studies in the United-States) about the impact of migrants on host country wages: some economists find only a small impact of migration on wages (Card, 2001), whereas others find a strong negative impact (Borjas, 2003) or a strong positive impact (Ottaviano and Peri, 2006).

$^3$ We may alternatively assume that migrants are better informed about investment opportunities in their origin country, thus may get a higher return on investment than in other countries, including the host one.
We can then show that when the net migratory benefit (i.e. the differential between the host country wage and the migratory cost) is very high, Galor’s (1986) conclusion holds: migration is total. However, when the net migratory benefit is not too high, and when transaction costs relative to international money transfer are not too low, then there are several steady migratory equilibria that do not empty the developing country of its population. At difference with Carrington et al. (1996), our result is not driven by the migratory cost dynamics, but by the accumulation of capital related to invested remittances. While all equilibria are described in this paper, special emphasis is set on one steady, not-total equilibrium that can exist for the broadest range of parameters. In this equilibrium there is a positive relationship between the equilibrium number of migrants and the remitted amount per migrant. The latter is increasing with the host country wage and decreasing with transaction and migratory costs.

To test this result, we use data on twenty five Eastern Europe and Central Asia (EECA) countries from 2000. Migration has been an important dimension of the transition process of EECA countries and continues to be relevant as these countries move beyond transition. Nowadays, EECA accounts for one-third of all developing country emigration and Russia is the second largest immigration country worldwide (World Bank, 2006). An important element for our analysis, EECA migratory outflows seem to be driven essentially by the economic motive. Migrants’ remittances with respect to GDP are large by world standards in many countries of the region. In 1995, officially recorded remittances to the EECA region totalled over US$7.7 billion, amounting to 7.6% of the global total for remittances (US$102 billion); in 2000, it increased to over US$12.8 billion representing almost 10% of world remittances; and in 2005, it totalled over US$27.7 billion amounting to more than 10% of total remittances (World Development Indicators data). Like elsewhere in the world, in EECA countries remittances are partially spent on household consumption, and partially saved and invested, thus contributing to capital formation. In turn, wages in the migrants’ origin countries seem to rise in an accelerated way, and so does productivity.4

This picture is much in line with implications of our theoretical model. We will provide several

---

4 For example, according to the Financial Times, in Eastern Europe, wages in some sectors have risen up to 50% from mid-2006 to mid-2007 (Financial Times, June 5, 2007, Eastern Europe hit by shortage of workers). According to the Romania Monthly Economic Review (Sept. 2008, Ernst & Young SRL), in Romania, the national gross salary increased by 21.8% from 2006 to 2007.
OLS and bootstrap estimates of our key relationship between the total number of migrants and remittances per migrant. The estimated elasticity turns out to be positive, in keeping with the theoretical arguments.

Finally, we analyze migratory policies that have to be implemented in order to make the equilibrium situation optimal from the standpoint of the developing country. We assume that public policies can use two levers of action: they can modify either the migratory cost, or the international transaction costs. We show that for an utilitarian criterion, there exists a single combination of migratory and international transaction costs that makes the equilibrium optimal; the migratory cost is then a decreasing function of international transaction costs. Out of this optimal policy, the number of migrants is in general lower than the optimal number, a conclusion that has already reached by Schiff (2002) in a different framework.

The paper is organized as follows. The next section introduces a two-country two-period migratory model, and particularly analyses the level of remittances and the wage rate in the origin country of migrants. The existence and properties of the migratory equilibrium are analyzed in Section 3. Section 4 uses the EECA 2000 data to provide an empirical assessment of the link between invested remittances and the equilibrium number of migrants. Section 5 analyses the optimal migratory policies. The final section concludes the paper.

2 The model

2.1 Economic context and notations

The model analyses the equilibrium with migration within a two-period set-up. The worker earns a wage income only at the first period; he consumes at both the first and the second period. There are two countries: one developing country, which is the migrants’ origin, and a developed country, which is the migrants’ destination. At the beginning at the first period, the worker decides whether to migrate or not. If he migrates, he earns a wage income abroad (in a "hard" currency), can save and invest in his home country; at the second period, he gets a positive return from his investment. If he does not migrate, his total consumption is bounded by his first period wage (imperfect financial markets do not provide for appropriate saving instruments). More in
detail, the economic structure of the two countries is:

- The developed (host) country.

The developed country is assumed to be big relatively to the developing country. The migrants’ wage rate in the developed country, denoted by $s$, is exogenously given; furthermore, the demand for migrant labor is infinitely elastic at this wage (all migrants can get a job at this rate).

- The developing (origin) country.

In the origin country, output is produced with labor $L$ and capital $K$, according to a standard neoclassical production function, $y = F(K, L)$.

We assume that labour is homogeneous and that individuals are all identical (same skills and consumption preferences). Each individual provides one unit of labor inelastically. Without migration, the total labor supply in the origin country is $L_0$. If there are $M$ migrants, available labor becomes $L = L_0 - M$. The mobility of labor is imperfect, migrants are subject to a migration cost, $c$.

Each migrant remits a gross amount of resources $T$ towards his origin country. The cost of transferring resources is $\tau$, the net amount transferred is $T - \tau$.

Without migration, capital in the origin country is $K_0$. We assume that remittances provide for the only source of accumulating capital in the developing country. Net remittances are reinvested in capital. Hence, if there are $M$ migrants, the amount of capital becomes:

$$K = K_0 + M(T - \tau). \quad (1)$$

Return on capital in the origin country is given, and will be denoted by $r$, which can be seen as the world interest rate plus a premium due to imperfections in the financial market of this country.

Let $w$ denote the worker wage in the origin country. Labor market is highly flexible, the wage rate clears the labor market.

---

5 This amount will be determined later on. Since workers from the developing country are all identicals, they each remit the same amount to their origin country.

6 The structure of the model would not change if we consider that only a fraction of the remittances were invested.
Finally, we assume that the population growth rate is null during the time period under study and that capital does not depreciate.

To make the analysis tractable, we consider that the production function is of a constant-returns to scale Cobb-Douglas type:

\[ y = F(K, L) = AK^aL^{1-a}, \]  

with \( A > 0 \) and \( a < 1 \).

We denote by \( k = \frac{K}{L} \) the capital intensity in the developing country. Without migration, the capital intensity is: \( k_0 = \frac{K_0}{L_0} \). If there are \( M \) migrants, the capital intensity becomes:

\[ k(M) = \frac{K_0 + M(T - \tau)}{L_0 - M}, \]  

with \( k(0) = k_0 \). Here \( k(M) \) is an increasing function in the number of migrants.

The marginal product of labor and capital are respectively \( MP_L(k) = (1 - a)A(k)^a \) and \( MP_K(k) = aA(k)^{a-1} \).

Finally, when borders are closed, capital is scarce and the marginal productivity of capital is higher than the return on capital. Formally, it implies:

\[ MP_K(k_0) > r \iff k_0 < \left( \frac{aA}{r} \right)^{\frac{1}{1-a}}. \]  

2.2 Optimal remittances

If a worker became a migrant, at the first period (index 0), he earns a wage \( s \), must pay the constant migratory cost \( c \), and eventually remits an amount \( T \). At the second period (index 1), he has no earnings, but he can consume his savings.

The migratory cost \( c \) includes financial costs (traveling costs, relocation costs...), psychological costs (of being far away from home and the loved ones...) as well as costs linked to the migratory policy (costs to obtain a visa, costs of administrative procedure...). We admit that the migratory cost is lower than the wage rate in the origin country. Hence, all workers who want to migrate can pay the cost without having to borrow.

To keep the problem simple, we assume that all the migrant’s savings will be invested in the origin country, by means of remittances. We have defined the cross-border transaction cost by

\[ \text{See Carrington et al. (1996) for a model of migratory equilibria with migratory costs depending on the number of migrants.} \]
We assume that this cost has a fixed part and a variable part proportional to the remitted amount: 
\[ \tau = \beta + (1 - \alpha) T, \] with \( \alpha < 1 \) and \( \beta > 0 \). Hence, the net transfer, denoted by \( R \), can be written: 
\[ R = T - \tau = \alpha T - \beta. \]

The first trade-off of the migrant is whether or not he should invest in his origin country. We assume that as long as his investment is not constrained (i.e. there are available projects), he prefers to save and invest than not, i.e. that his utility when remitting and investing his optimal amount is higher than his utility when he does not invest. We assume that the conditions on the parameters implied by this assumption are met (see Appendix A.1.).

Available projects exist as long as the marginal productivity of capital is higher than the interest rate required by investors. This implies the following condition:

\[ MP_{K}(k) \geq r \iff k(M) \leq \left( \frac{aA}{r} \right)^{\frac{1}{1-\sigma}} \iff M \leq M_1 \equiv \frac{1 - \left( \frac{r}{aA} \right)^{\frac{1}{1-\sigma}} k_0}{1 + \left( \frac{r}{aA} \right)^{\frac{1}{1-\sigma}} R}. \] (5)

Thus, as long as there are less than \( M_1 \) migrants, migrants can invest an optimal amount. When there are exactly \( M_1 \) migrants, then the capital intensity is equal to \( k(M_1) = \left( \frac{aA}{r} \right)^{\frac{1}{1-\sigma}} \). When the number of migrants is above \( M_1 \), investment, and in particular invested remittances, are constrained since capital intensity cannot be higher than \( k(M_1) \) (otherwise, the marginal productivity of capital would be lower than its cost).

We assume that when invested remittances are constrained, migrants equally share the total amount that can be invested in their origin country. Finally, we show that when migration reaches a certain threshold \( M_2 \), migrants prefer not to invest in their origin country (see Appendix A.1.).

Formally, there are three different cases:

- **1st case**: no investment constraint, \( M \leq M_1 \)

If \( C_{0m} \) is consumption at the beginning of the period and \( C_{1m} \) is final consumption, the optimization program of the migrant is:

\[
\begin{align*}
\max_{(C_{0m}, C_{1m})} & \quad U(C_{0m}, C_{1m}) \\
\text{s.t.} & \quad C_{0m} = s - c - T > 0 \\
& \quad \text{and } C_{1m} = (1 + r) (\alpha T - \beta) > 0.
\end{align*}
\] (6)
In order to obtain explicit forms, we assume that: 
\[ U(C_{0m}, C_{1m}) = \ln C_{0m} + \frac{1}{1+\rho} \ln C_{1m} \]
where \( \rho \) is representative of the individual’s preference for present consumption (0 ≤ \( \rho \) ≤ 1).

The maximization program becomes:

\[
\begin{align*}
\max_T & \quad \ln C_{0m} + \frac{1}{1+\rho} \ln C_{1m} \\
\text{s.t.} & \quad C_{0m} = s - c - T > 0 \\
& \quad C_{1m} = (1 + r) (\alpha T - \beta) > 0.
\end{align*}
\]

(7)

The first order condition \( dU(C_{0m}(T), C_{1m}(T))/dT = 0 \) implies:

\[
\begin{align*}
T_0 &= \frac{1}{2 + \rho} \left[ (s - c) + (1 + \rho) \frac{\beta}{\alpha} \right] > 0 \\
R_0 &= \frac{1}{2 + \rho} [\alpha (s - c) - \beta]
\end{align*}
\]

(8) (9)

We check that \( C_{0m} > 0 \) and \( C_{1m} > 0 \) if and only if \( \alpha (s - c) - \beta > 0 \), that is if the ratio between the fixed and the variable transaction costs is lower than the host country wage net of migratory cost \( \left( \frac{\beta}{\alpha} < s - c \right) \). We assume that this condition is fulfilled. Thus, the optimal remitted amount \( R_0 \) strictly positive.

According to Equations (8) and (9), both the gross and net remittances per head are linearly increasing functions in the host country wage net of the migratory cost, \( (s - c) \). Net remittances per migrant are a decreasing function of transaction costs. In this configuration, the optimal amount of remittances per migrant is independent of the number of migrants; changes in remittances per migrant are driven only by (exogenous) shocks to parameters.

For the optimal transfer, the indirect utility of the migrant can be written:

\[
U(C_{0m}^*, C_{1m}^*) = \ln \left\{ \frac{1}{\alpha} \left( \frac{1 + \rho}{2 + \rho} \right)^\frac{1}{1+\rho} \left[ \alpha (s - c) - \beta \right]^\frac{\alpha}{1+\rho} \right\} = \ln (V_0),
\]

(10)

with:

\[
V_0 = \frac{1}{\alpha} \left( \frac{1 + \rho}{2 + \rho} \right)^\frac{1}{1+\rho} \left[ \alpha (s - c) - \beta \right]^\frac{\alpha}{1+\rho} = \frac{1}{\alpha} (1 + \rho) (1 + r)^\frac{1}{1+\rho} R_0^\frac{\alpha}{1+\rho}.
\]

(11)

The indirect utility \( V_0 \) is increasing in the net remitted amount, \( \frac{\partial V_0}{\partial R_0} > 0 \). Yet, we have shown that the net remitted amount \( R_0 \) is increasing with the host country wage net of migratory cost \( (s - c) \). Thus, the indirect utility \( V_0 \) have a similar response to variations in \( (s - c) \):
\[
\frac{\partial V_0}{\partial (s-c)} = \frac{\partial V_0}{\partial R_0} \frac{\partial R_0}{\partial (s-c)} > 0.
\] (12)

It can also be checked that \( V_0 \) is decreasing with transaction costs:

\[
\frac{\partial V_0}{\partial \beta} = -\left( \frac{2 + \rho}{1 + \rho} \right) \frac{V_0}{\alpha (s-c) - \beta} < 0 \quad \text{(13)}
\]

\[
\frac{\partial V_0}{\partial \alpha} = \frac{V_0}{\alpha (1 + \rho) [\alpha (s-c) - \beta]} [\alpha (s-c) + (1 + \rho) \beta] > 0. \quad \text{(14)}
\]

- 2nd case: constrained investment, \( M_1 < M \leq M_2 \)

The remitted amount per migrant is constrained. Indeed, if each migrant were remitting and investing the optimal amount \( R_0 = \frac{1}{2 + \rho} [\alpha (s-c) - \beta] \), then the marginal productivity of capital would be lower than the interest rate \( r \), which is impossible. Necessarily, migrants remit and invest an amount \( R_1 (M) \) such that the marginal productivity of capital is at the most equal to \( r \). In other words, the net remitted amount, \( R_1 (M) \), is such that:

\[
\frac{K_0 + MR_1 (M)}{L_0 - M} \leq \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}}
\]

\[
R_1 (M) \leq \frac{1}{M} \left[ (L_0 - M) \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}} - K_0 \right]
\]

\[
T_1 (M) \leq \frac{1}{\alpha M} \left[ (L_0 - M) \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}} - K_0 \right] + \frac{\beta}{\alpha}.
\] (15)

Thus, the optimization program of the migrant is modified when \( M \) varies between \( M_1 \) and \( M_2 \):

\[
\begin{align*}
\text{max} & \quad \ln C_{0m} + \frac{1}{1 + \rho} \ln C_{1m} \\
\text{s.t.} & \quad C_{0m} = s - c - T (M) > 0 \\
& \quad C_{1m} = (1 + r) (\alpha T (M) - \beta) > 0 \\
& \quad T (M) \leq \frac{1}{\alpha M} \left[ (L_0 - M) \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}} - K_0 \right] + \frac{\beta}{\alpha}.
\end{align*}
\] (16)

Solving the program implies:

\[
T_1 (M) = \frac{1}{\alpha M} \left[ (L_0 - M) \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}} - K_0 \right] + \frac{\beta}{\alpha}, \text{ decreasing in } M; \quad \text{(17)}
\]

\[
R_1 (M) = \frac{1}{M} \left[ (L_0 - M) \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}} - K_0 \right] < \frac{1}{2 + \rho} [\alpha (s-c) - \beta], \text{ decreasing in } M. \quad \text{(18)}
\]

Notice that when there are between \( M_1 \) and \( M_2 \) migrants, the remitted amount per migrant is such that the marginal productivity of capital is constant and equal to \( r \): \( \forall M \in [M_1; M_2] \), \( k(M) = k(M_1) = \left( \frac{aA}{r} \right)^{\frac{1}{1 + \rho}}. \)
It can be easily checked that for any \( M \) ranging between \( M_1 \) and \( M_2 \), initial and final consumptions are strictly positive.

For this remitted amount, the indirect utility of the migrant is:

\[
U(C_{0m}^*, C_{1m}^*) = \ln \left\{ \left( \frac{1 + r}{\alpha} \right)^{\frac{s - c}{2 + \rho}} [R_1(M)]^{\frac{s - c}{2 + \rho}} [\alpha (s - c) - \beta - R_1(M)] \right\} = \ln \left[ V_1(M) \right], \quad (19)
\]

with:

\[
V_1(M) \equiv \frac{(1 + r)}{\alpha} [R_1(M)]^{\frac{1 - \alpha}{2 + \rho}} [\alpha (s - c) - \beta - R_1(M)]. \quad (20)
\]

It can be easily checked that \( V_1(M) \) is decreasing with the number of migrants \( M \):

\[
\frac{\partial V_1}{\partial M} = \frac{\partial V_1}{\partial R_1} \frac{\partial R_1}{\partial M} = \frac{(1 + r)}{\alpha} [R_1(M)]^{\frac{1 - \alpha}{2 + \rho} - 1} [\alpha (s - c) - \beta - (2 + \rho) R_1(M)] \frac{\partial R_1}{\partial M}.
\]

Yet \( R_1(M) < R_0 \) thus \( [\alpha (s - c) - \beta - (2 + \rho) R_1(M)] > 0 \) and \( \frac{\partial V_1}{\partial M} < 0 \).

- 3\(^{rd}\) case: no investment, \( M_2 < M < L_0 \)

When migration reaches the threshold \( M_2 \), migrants prefer not to invest in their origin country; remittances are then null. Indeed, when migration reaches \( M_2 \), the capital intensity is lower than \((\frac{a\delta}{r})^{\frac{1}{1+\rho}}\) for any remitted amount (the existence and properties of \( M_2 \) are studied in Appendix A.1.).

Thus, the optimization program of the migrant is modified when \( M \) ranges between \( M_2 \) and \( L_0 \):

\[
\begin{array}{l}
\max(C_{0m}, C_{1m}) \left[ \ln C_{0m} + \frac{s - c}{2 + \rho} \ln C_{1m} \right] \\
\text{s.t. } C_{0m} + C_{1m} = s - c.
\end{array} \quad (21)
\]

Solving the program implies: \( C_{0m}^* = \left( 1 + \rho \right) \left( \frac{s - c}{2 + \rho} \right) > 0 \) and \( C_{1m}^* = \left( \frac{s - c}{2 + \rho} \right) > 0 \). For these consumption levels, the indirect utility of the migrant is:

\[
U(C_{0m}^*, C_{1m}^*) = \ln \left\{ \left( 1 + \rho \right) \left( \frac{s - c}{2 + \rho} \right)^{\frac{2 + \rho}{2 + \rho}} \right\} \quad (22)
\]

\[
U(C_{0m}^*, C_{1m}^*) = \ln (V_2), \quad \text{with } V_2 \equiv \left( 1 + \rho \right) \left( \frac{s - c}{2 + \rho} \right)^{\frac{2 + \rho}{2 + \rho}}. \quad (23)
\]
2.3 The indirect utility of the migrant

Thus, we can define two functions, \( R(M) \) and \( V(M) \), respectively representing the net remitted amount per migrant and (the exponential of) the indirect utility of the migrant:

\[
R(M) = \begin{cases} 
R_0 = \frac{\alpha (s-c) - \beta}{2 + \rho} & \forall M \in [0; M_1] \\
R_1(M) = \frac{1}{\alpha} \left[ (L_0 - M) \left( \frac{aA}{r} \right)^{\frac{1}{s-a}} - K_0 \right] & \forall M \in [M_1; M_2] \\
R_2 = 0 & \forall M \in [L_0] 
\end{cases} 
\quad (24)
\]

\[
V(M) = \begin{cases} 
V_0 = \frac{1}{\alpha} (1 + \rho) (1 + r)^{\frac{1}{s+a}} R_0 \frac{2 + \rho}{2 + a} & \forall M \in [0; M_1] \\
V_1(M) = \frac{(1 + \rho)^{\frac{1}{s+a}}}{\alpha} \left[ R_1(M) \right]^{\frac{1}{s+a}} \left[ (2 + \rho) R_0 - R_1(M) \right] & \forall M \in [M_1; M_2] \\
V_2 = (1 + \rho) \left( \frac{s-c}{2 + \rho} \right) \frac{2 + \rho}{2 + a} & \forall M \in [L_0] 
\end{cases} 
\quad (25)
\]

2.4 The developing country wage

For the time being, we assume that the number of migrants \( M \) is exogenous. Later on, we will show how the number of migrants is determined as an equilibrium value.

Labor is remunerated with the residual from the sell of the output and the cost of capital:

\[ wL = A(K)^a (L)^{1-a} - rK^a. \]

The equilibrium wage rate \( w \) is:

\[ w(k) = A(k)^a - rk. \quad (26) \]

The assumption according to which the marginal productivity of capital is higher than the interest rate without migration (equation 4) implies that the wage rate without migration is positive:

\[ k_0 < \left( \frac{aA}{r} \right)^{\frac{1}{s+a}} \implies k_0 < \left( \frac{A}{r} \right)^{\frac{1}{s+a}} \implies w_0 > 0. \]

According to equation (26), the wage rate depends on the capital intensity. Thus, there is a need to distinguish between three different cases.

- **1\textsuperscript{st} case**: \( M \leq M_1 \) (no investment constraint)

Then, the remitted amount per migrant is \( R_0 \), independent from \( M \). The capital intensity becomes:

\[ k(M) = \frac{K_0 + MR_0}{L_0 - M}. \quad (27) \]

\(^8\) Here, remittances do not have a negative impact on labour supply because they are invested and not sent for altruistic reasons (Chami et al., 2005; Naiditch and Vranceanu, 2009), nor for an insurance motive (Azam et Gubert, 2005).
The wage rate in the developing country then is:

\[
w(M) = A \left( \frac{K_0 + MR_0}{L_0 - M} \right)^a - r \left( \frac{K_0 + MR_0}{L_0 - M} \right).
\]  

(28)

with \( w(M = 0) = A (k_0)^a - r k_0 = w_0 > 0 \) and \( \lim_{M \to M_1} w(M) = w(M_1) = (1 - a) A^{\frac{1}{a}} \left( \frac{a}{r} \right)^{\frac{1}{a}} \).

- 2nd case: \( M_1 < M \leq M_2 \) (constrained investment)

Then, the remitted amount per migrant is \( R_1(M) \) such that: \( \forall M, k(M) = k(M_1) = (\frac{aA}{r})^{\frac{1}{a}} \).

The wage rate in the developing country is:

\[
w(M) = w(M_1) = (1 - a) A^{\frac{1}{a}} \left( \frac{a}{r} \right)^{\frac{1}{a}}.
\]  

(29)

- 3rd case: \( M_2 < M < L_0 \) (no investment)

Then, the remitted amount per migrant is null; the capital intensity becomes: \( \forall M, k(M) = \frac{K_0}{L_0 - M} \leq (\frac{aA}{r})^{\frac{1}{a}} \).

The wage in the developing country is:

\[
w(M) = A \left( \frac{K_0}{L_0 - M} \right)^a - r \left( \frac{K_0}{L_0 - M} \right).
\]  

(30)

If we were to summarize the three cases, we can define a function \( w \) representing the wage in the developing country depending on \( M \):

\[
w(M) = \begin{cases} 
A \left( \frac{K_0 + MR_0}{L_0 - M} \right)^a - r \left( \frac{K_0 + MR_0}{L_0 - M} \right) & \forall M \in [0; M_1] \\
(1 - a) A^{\frac{1}{a}} \left( \frac{a}{r} \right)^{\frac{1}{a}} = w(M_1) & \forall M \in [M_1; M_2] \\
A \left( \frac{K_0}{L_0 - M} \right)^a - r \left( \frac{K_0}{L_0 - M} \right) & \forall M \in [M_2; L_0[ 
\end{cases}
\]  

(31)

**Proposition 1** The wage in the developing country is an increasing function of the number of migrants over \([0; M_1]\). It is a constant function of the number of migrants over \([M_1; M_2]\). There is a discontinuity in \( M_2 \); it increases and then decreases over \([M_2; L_0[\). It reaches its maximum over \([M_1; M_2]\) and in \( M_1 = L_0 - \left( \frac{r}{aA} \right)^{\frac{1}{a}} K_0 \). It is null when the emigration level reaches the threshold \( M_4 \equiv L_0 - \left( \frac{r}{aA} \right)^{\frac{1}{a}} K_0 \).

**Proof.** The proof can be found in Appendix A.2. 

Figure 1 depicts the wage as a function of \( M \).
The wage rate in the developing country.

The wage rate in the developing country reaches its maximum over \([M_1; M_2]\) and then again in \(M_3\):

\[
w(M_1) = w(M_3) = (1 - a) A^{\frac{1}{1-a}} \left( \frac{A}{R} \right)^{1-a} > w_0 > 0.
\]

We can notice that the maximum wage is independent from the remitted amount. It is reached for the first time in \(M_1\) which decreases with \(R_0\). Thus, the higher the optimal remitted amount per migrant, the faster the maximum wage is reached. Yet, for any migration level below \(M_1\), the net remitted amount increases with the net benefit from migration and decreases with transaction costs. Thus, the higher the host country wage and the lower the migratory and transaction costs, the faster the maximum wage is reached.

2.5 The indirect utility of the resident

At the beginning of the period 0, the resident earns a wage \(w(M)\). To keep the model simple, we assume that due to imperfections in the financial markets he cannot invest in productive activities (he can save money, but at a zero interest rate).

Then, if \(C_{0r}\) is the resident’s consumption at the beginning of the period and \(C_{1r}\) his final consumption, his optimization program is:

\[
\begin{align*}
\text{max}_{(C_{0r}, C_{1r})} & \quad U(C_{0r}, C_{1r}) \\
\text{s.t.} & \quad C_{0r} + C_{1r} = w(M) \\
& \quad \text{and} \quad C_{0r} > 0, \ C_{1r} > 0.
\end{align*}
\]
We assume that the resident and the migrant have the same utility function and the same preference for present consumption: $U(C_{0r}, C_{1r}) = \ln C_{0r} + \frac{1}{1+\rho} \ln C_{1r}$.

The optimization program of the resident becomes:

$$\begin{align*}
\max_{C_{0r}, C_{1r}} \left[ \ln C_{0r} + \frac{1}{1+\rho} \ln (w(M) - C_{0r}) \right] \\
s.t. \ 0 < C_{0r} < w(M).
\end{align*}$$

The first order condition $dU(C_{0r})/dC_{0r} = 0$ implies:

$$\begin{align*}
C^*_0 &= \left( \frac{1+\rho}{2+\rho} \right) w(M) > 0 \\
C^*_1 &= \left( \frac{1}{2+\rho} \right) w(M) > 0
\end{align*}$$

For optimal consumption levels, the indirect utility of the resident is:

$$U(C^*_0, C^*_1) = \ln \left( \left( \frac{1+\rho}{2+\rho} \right) \left( \frac{1}{2+\rho} \right) w(M) \frac{1+\rho}{1+\rho} \right)$$

$$U(C^*_0, C^*_1) = \ln (W(M)) \text{, with } W(M) \equiv \left( \frac{1+\rho}{2+\rho} \right) \left( \frac{1}{2+\rho} \right) w(M) \frac{1+\rho}{1+\rho}. \quad (34)$$

We previously showed that the wage in the developing country depends on the number of migrants. We can then define the function $W$ representing (the exponential of) the indirect utility of the resident:

$$W(M) = \begin{cases} 
W_0 (M) & \equiv \left( \frac{1+\rho}{2+\rho} \right) ^{\frac{1+\rho}{1+\rho}} \left\{ A \left[ \frac{K_0 + MR_0}{K_0 - M} \right]^a - r \left[ \frac{K_0 + MR_0}{K_0 - M} \right] \right\}^{\frac{1+\rho}{1+\rho}} \quad \forall M \in [0; M_1] \\
W_1 (M) & \equiv \left( \frac{1+\rho}{2+\rho} \right) ^{\frac{1+\rho}{1+\rho}} \left\{ (1-a) A \left( \frac{K_0}{L_0 - M} \right)^a \right\}^{\frac{1+\rho}{1+\rho}} \quad \forall M \in ]M_1; M_2] \\
W_2 (M) & \equiv \left( \frac{1+\rho}{2+\rho} \right) ^{\frac{1+\rho}{1+\rho}} \left\{ A \left[ \frac{K_0}{L_0 - M} \right]^a - r \left[ \frac{K_0}{L_0 - M} \right] \right\}^{\frac{1+\rho}{1+\rho}} \quad \forall M \in ]M_2; L_0[. 
\end{cases} \quad (35)$$

### 3 Migratory equilibria

#### 3.1 The equilibrium number of migrants

In autarky all the citizens of the developing country work in their origin country and are paid the wage rate $w_0$. When migration is allowed, individuals have to make a choice: they can either stay in their origin country and be paid the wage rate $w(M)$, or migrate to the developed country. If they migrate, they get paid the wage rate $s$, need to pay a constant migratory cost $c$, and can remit a gross amount $T$ of which a part $R$ is invested in their origin country.

The worker chooses his location in order to maximize his utility. Thus, he decides to migrate if his utility in case of migration is higher than his utility when remaining in his origin country.
His decision to migrate thus depends on anticipated wages in both countries, on migratory and transaction costs and on the prospective return on his investment.

Our definition of equilibrium implies an implicit dynamics, with workers leaving one after the other (but, why not, at a very short interval). As all workers are identical in this model, who does migrate before the other ultimately depends on "the speed of packing luggage". At the migratory equilibrium, the marginal worker (i.e. the worker whose turn has come to take the decision) is indifferent between migrating to the developed country and staying in the origin country. In equilibrium, migrants’ utility is identical to the stayers’ utility.

Formally, the equilibrium condition is:

\[
\ln V(M^*) = \ln W(M^*). \tag{36}
\]

Formally, it means:

\[
\begin{align*}
V_0 &= W_0(M), & M^* \in [0; M_1] \\
V_1(M^*) &= W_1, & M^* \in [M_1; M_2] \\
V_2 &= W_2(M), & M^* \in [M_2; L_0]
\end{align*} \tag{37}
\]

**Proposition 2** There are four types of equilibria:

- When \( V_2 > W_1 \), there is total migration (equilibrium 0).
- When \( V_2 \leq W_1 < V_0 \), there are one or two steady equilibria: one between \( M_1 \) and \( M_2 \) and the other between \( M_2 \) and \( M_3 \) (only under certain conditions) (equilibrium 1).
- When \( W_0 < V_0 \leq W_1 \), there is a single steady equilibrium before \( M_1 \) (\( M^* \)). Under certain conditions, there exists another steady migratory equilibrium between \( M_2 \) and \( M_3 \) (equilibrium 2).
- When \( V_0 \leq W_0 \), there is no migration (equilibrium 3).

**Proof.** The proof can be found in Appendix A.3. ■

Figure 2 displays the various possible equilibria, depending on the parameters of the problem.
Thus, there may be total emigration at the equilibrium (equilibrium 0): when \( V_2 > W(M_1) \), the developing country is deserted at the equilibrium. Galor’s result (1986) holds despite invested remittances. Formally, there is total migration when \( V_2 > W(M_1) \iff (s - c) > w(M_1) \). In other words, there is total migration when the migratory cost is too low, whatever the level of transaction costs:

\[
V_2 > W(M_1) \iff c < s - (1 - a) A^{\frac{1}{1+a}} \left( \frac{a}{r} \right)^{\frac{r}{a+r}}. \tag{38}
\]

There is a high steady equilibrium (between \( M_1 \) and \( M_2 \), equilibrium 1) when the migratory cost (function of transaction costs) is low, but not too low:

\[
V_2 \leq W(M_1) < V_0 \iff s - (1 - a) A^{\frac{1}{1+a}} \left( \frac{a}{r} \right)^{\frac{r}{a+r}} \leq c < s - \frac{\beta}{\alpha} \frac{(1 - a) A^{\frac{1}{1+a}} \left( \frac{r}{a} \right)^{\frac{r}{a+r}}}{[\alpha (1 + r)]^{\frac{r}{1+a}}}. \tag{39}
\]
There is a steady migratory equilibrium below $M_1$ (equilibrium 2) when the migratory cost (function of transaction costs) is neither too low, nor too high:

$$W_0 < V_0 \leq W(M_1) \iff s - \frac{\beta}{\alpha} = \frac{(1 - \alpha) A^{1+\rho} (\frac{s}{\alpha})^{\frac{\alpha}{1+\rho}}}{\alpha (1 + \rho) (1 + r)^{\frac{\alpha}{1+\rho}}} \leq c < s - \frac{\beta}{\alpha} - \frac{(A(k_0)^a - r(k_0))}{\alpha (1 + r)^{\frac{\alpha}{1+\rho}}}.$$  \hspace{1cm} (40)

Finally, there is no migration at all (equilibrium 3) when the migratory cost (function of transaction costs) is too high:

$$V_0 \leq W_0 \iff c \geq s - \frac{\beta}{\alpha} - \frac{(A(k_0)^a - r(k_0))}{\alpha (1 + r)^{\frac{\alpha}{1+\rho}}}.$$ \hspace{1cm} (41)

For the sake of parsimony, we study hereafter only the Equilibrium 2. Indeed, this equilibrium is non total, that is not all the residents leave the developing country; this seems to be a general migration pattern. Furthermore, compared to configuration 1 (two stable non-total equilibria), Equilibrium 2 is likely to occur for the broadest range of parameters.

3.2 Properties of the Equilibrium 2

Let $M^*$ denote the equilibrium number of migrants. In this configuration, the equilibrium number of migrants is below $M_1 : M^* \leq M_1$ (with utilities ranked: $\ln W_0 < \ln V_0 \leq \ln W(M_1)$). We denote by $k^*$ the capital intensity when migration reaches $M^*$.

Thus, any migrant’s utility is $\ln V_0 = \ln \left[ \frac{1}{\alpha} (1 + \rho) (1 + r)^\frac{\alpha}{1+\rho} R_0^{\frac{\alpha}{1+\rho}} \right]$, and any resident’s utility is $\ln W_0(M) = \ln \left[ \left( \frac{1}{\alpha} \right)^{\frac{\alpha}{1+\rho}} \left( \frac{1}{\alpha} \right)^{\frac{\alpha}{1+\rho}} A \left[ \frac{K_o + M R_0}{k_0 - M} \right]^a - r \left[ \frac{K_o + M R_0}{k_0 - M} \right]^{\frac{\alpha}{1+\rho}} \right]$.

How does the equilibrium number of migrants vary with the gross and net remitted amounts?

and with migratory and transaction costs?

We have shown (equation 9) that for $M < M_1$, the optimal amount of remittances $R_0 = \frac{1}{\alpha} (s - c) - \beta$ depends on $(s - c)$, $\alpha$ and $\beta$. Changes in these parameters (for instance an increase in the host country wage $s$) induces changes in the remitted amount. In turn, changes in parameters that push up the remitted amount per migrant, also push up the migrant’s indirect utility $V_0$.

On the other hand, for a constant number of migrants below $M_1$, the wage in the origin country $w(M)$ is an increasing function of the remitted amount per migrant. Indeed, according to equation
(26), we know that: 
\[ \frac{\partial \mu_{\ell}(M)}{\partial h_0} \geq 0 \iff \left[ aA(k(M))^{a-1} - r \right] \frac{\partial k(M)}{\partial h_0} \geq 0 \iff k(M) \leq \left( \frac{aA}{\beta} \right)^{1/a} \iff M \leq M_1. \]

Thus, for a constant number of migrants below \( M_1 \), both residents and migrants’ utilities increase when changes in parameters push up the optimal remitted amount. The increase in the residents’ utility has a negative effect on the equilibrium number of migrants, whereas the increase in the migrants’ utility has a positive effect on the equilibrium number of migrants. In our framework, we can show that:

**Proposition 3** The equilibrium number of migrants \( M^* \) and the optimal amount of remittances per migrant \( R_0 \) are positively related.

**Proof.** The proof can be found in Appendix A.4.  

When remittances per migrant increase, the induced increase in the migrant’s utility is higher than the induced increase in the resident’s utility. Note that \( M^* \) is an increasing function of the remitted amount whereas \( M_1 \) is a decreasing function of remittances.

**Proposition 4** The higher the net migratory benefit \( s - c \), the higher the equilibrium migration \( M^* \), and the higher the remittances per migrant \( R_0 \). The smaller the fixed transaction costs \( \beta \), the higher the equilibrium migration \( M^* \), and the higher the remittances per migrant \( R_0 \). If \( a \leq \frac{1}{\alpha \beta} \), the smaller the variable transaction costs \( (1 - \alpha) \) the higher the equilibrium migration \( M^* \), and the higher the remittances per migrant \( R_0 \).

**Proof.** The proof of the first part of these sentences can be found in Appendix A.4. The second part, pertaining to the relationship between parameters and optimal remittances directly follow from equation (11).  

In equilibrium, shocks to parameters move both remittances per migrant and the total number of migrants in the same direction. As a consequence, if this equilibrium prevails, one should observe a positive correlation between the amount of remittances per migrant and the equilibrium number of migrants.

Figure 3 illustrates the mechanism at work.
Impact of an increase of the net migratory benefit.

The initial equilibrium is obtained for $V_0 = W(M)$, where the number of migrants is $M^*$. A utility increasing shock (e.g. $s$ increases) would lead to higher optimal remittances and more investment, thus shifting $W(M)$ upwards (the blue positive slope curve). All things equal, the number of migrant would decline. Yet, the increase in $s$ (and in remittances that are invested) implies a higher utility for the migrants too, which goes to $V'0$ (blue horizontal line). The new equilibrium is obtained for $M'^*$. The net migratory effect is positive $M'^* > M^*$, (but smaller as compared to the situation where remittances cannot be invested, thus do not push up wages in the origin country).

In the next section, we aim at backing the theoretical model with some empirical evidence. Despite the substantial interest in this field, suitable data on remittances are so far very scarce; in particular, data on migratory costs and transaction costs are not available for a large group of countries; therefore, we could not test directly the relationships stated in Proposition 4. As a second best solution, we will analyze the equilibrium comovement between remittances per migrant and total number of migrants (Proposition 3).

4 The empirical analysis

4.1 The EECA region

Countries under scrutiny belong to the group of formerly centrally planned economies in Eastern Europe and Central Asia (EECA hereafter), and build on the World Bank’s official delineation of
the zone. In 2006, there were 28 countries in this group. Three countries had to be removed from the analysis (Tajikistan, Turkmenistan and Uzbekistan), since we did not have any information on the amount of remittances they received. Thus, we will study at most 25 countries.

This group of countries provides for a worthy case study, since they have a similar economic history; most important for our analysis, new migration is driven essentially by economic motives. The region also provides enough diversity in terms of development levels, growth in population and new migration to allow for meaningful tests of our model.

EECA countries total 444 million people. In 2000, the average crude birth rate in EECA countries was 12.7 per thousand people and the crude death rate was around 11.7 per thousand; net emigration represented 2.5 million people; globally, in 2000, the EECA population grew by 0.12% (WDI figures). More specifically, in 2000, most EECA countries saw their population decrease; in 4 countries, it grew by less than 1% (Slovenia, Montenegro, Macedonia, FYR, Azerbaijan); and in only 6 countries, the population growth rate was between 1% and 2.1% (Uzbekistan, Kyrgyzstan, Tajikistan, Turkmenistan, Turkey, Bosnia and Herzegovina).

According to a recent study by the World Bank (2006), migration flows in EECA tend to move in a largely bipolar pattern. Much of the emigration in Western EECA (42%) is directed toward Western Europe, while much emigration from the CIS remains within the CIS (80%). Germany is the most important destination country outside EECA for migrants from the region, while Israel was an important destination in the first half of the 1990s. Russia is the main intra-CIS destination. The United Kingdom is becoming a destination for migrants from the EECA countries of the European Union (EU). In 2000, according to the Global Migrant Origin Database, the largest stocks of migrants from EECA were located in Russia (11,553,062), Ukraine (6,669,273), Germany (3,883,761), Kazakhstan (2,838,336), the United States (2,177,586), Belarus (1,270,862),

---

9 The World Bank includes in its "Europe and Central Asia" group of countries: Albania, Armenia, Azerbaijan, Belarus, Bosnia and Herzegovina, Bulgaria, Croatia, Czech Republic, Estonia, the Former Yugoslav Republic of (FYR) Macedonia, Georgia, Hungary, Kazakhstan, Kyrgyzstan, Latvia, Lithuania, Moldova, Poland, Romania, Russian Federation, Serbia and Montenegro, Slovak Republic, Slovenia, Tajikistan, Turkey, Turkmenistan, Ukraine, and Uzbekistan.

10 Western ECA: the EU-10 new member countries, plus Bosnia and Herzegovina, Serbia, Montenegro, Albania, Croatia, and FYR Macedonia.

11 CIS = Commonwealth of Independent States (Armenia, Azerbaijan, Belarus, Georgia, Kazakhstan, Kyrgyzstan, Moldova, Russia, Tajikistan, Turkmenistan, Ukraine and Uzbekistan).
Israel (1,216,672) and Uzbekistan (1,034,601).

For many EECA countries, remittances are the second most important source of external financing after foreign direct investment. They represented 0.87% of the region’s GDP in 1995, 1.45% in 2000 and 1.37% in 2005. But these figures hide wide disparities. In 2000, for example, remittances represented more than 10% of the GDP of Moldova (30.8%), Tajikistan, Armenia, Bosnia and Herzegovina, Albania, and Kyrgyzstan. It represented between 1% and 5% in several countries (Bulgaria, Georgia, Azerbaijan, Romania, Macedonia FYR, Croatia, Serbia and Montenegro, Latvia, Poland, Lithuania and Estonia). Finally, it represented less than 1% only in the following countries (Belarus, Czech Republic, Slovenia, Ukraine, Russian Federation, Kazakhstan, Hungary, Turkey and Slovak Republic) (WDI figures).

Generally remittance flows in EECA follow the same two-bloc pattern as migration. The EU is the main source of remittances, accounting for three quarters of the total, and the resource-rich CIS are the other main source, accounting for 10%. The amount contributed by the EU-10 countries is also significant (World Bank, 2006).

Results from surveys with returned migrants in EECA found that a non negligible share of remittances is invested in capital formation. The World Bank (2006) claims that if the majority of remittances are utilized for funding consumption of food and clothing, large quantities are also used for education and savings (over 10%); smaller amounts are spent on direct investment in business (less than 5%). For example, in Armenia, empirical evidence suggests that the propensity to save out of remittance income is high (almost 40%) and remarkably consistent across studies (Roberts et al., 2004). In Albania, a study conducted on the national level in 1998 suggests that 17% of the investments in small and medium size enterprises came from money accumulated while working abroad (Kule et al. 2002). Other sources claim that almost 30% of investments in Albanian small and middle sized enterprises were primarily financed by remittances from family members working abroad (INSTAT, 2003). Another survey conducted in the Korçë district in Albania in 2002 suggests that around 5% of receiving households use the money from remittances to invest

---

12 EU-10: the Czech Republic, Poland, Hungary, Slovakia, Slovenia, Latvia, Lithuania, Estonia, Bulgaria and Romania (the latter two countries joined the EU in 2007).
in non-farm business, and around 17% use remittances for agricultural investments (Arrehag et al., 2005). An IOM survey of Serbian households with relatives living in Switzerland conducted in two rural regions of Serbia in 2006 showed that approximately \(\frac{1}{4}\) of surveyed households have used remittances to expand agricultural production and 8% to invest in a business (SECO, 2007).

A World Bank survey (World Bank, 2006) shows that in Kyrgyzstan, 11% of households receiving remittances report saving remittances. In Tajikistan, about 9% report saving remittances and 2.5% report investing in business. In Moldova, according to a study conducted in 2006, nearly 30% of recipient households save over US$500 (Orozco, 2007).

4.2 Data and definition of main variables

4.2.1 Migration data

- Problems inherent to migration data

Compiling data on migration stocks and flows is quite complicated for several reasons. Official data often underestimate migrants stocks and flows because of difficulties that arise from differences across countries in the definition of a migrant (foreign born versus foreign nationality), reporting lags in census data, and under-reporting of irregular migration. These problems arise, in part due to a lack of standardized definitions and common reporting standards (and inadequate adherence to these standards where they exist). The commonly accepted UN definition describes a “migrant” as a person living outside his or her country of birth.

Some problems are more specific to EECA countries. Indeed, the type, direction and magnitude of the flows in the region have changed dramatically since the beginning of economic transition, liberalization of societies and retrieved human rights (including the cross-border freedom of movement), and the emergence of 22 new states. The extent to which the successor states have implemented statistic systems able to properly measure total migration flows and disaggregate these flows by nationality varies considerably. Moreover, the break-up of the Soviet Union, Yugoslavia, and Czechoslovakia created a large number of “statistical migrants”.\(^\text{13}\)

\(^{13}\) Statistical migrants refers to persons who migrated internally while those countries existed, thus not qualifying as a migrant under the UN definition at the time, but who began to be counted as migrants when those countries broke apart even though they did not move again (World Bank, 2006).
Databases

For the purpose of this paper, we need an estimate of the total stock of emigrants from each EECA country. To our knowledge, the only databases providing that information are the Global Migrant Origin Database (Migration DRC, University of Sussex) and the database prepared by the Development Prospects Group (World Bank).

We get the University of Sussex data from the Development Research Centre on Migration, Globalisation and Poverty (Migration DRC), an independent organization for the study of migrations. The data are generated by disaggregating the information on migrant stocks in each destination country or economy as given in its census to get a 226x226 matrix of origin-destination stocks by country. In essence, the Migration DRC database extends the basic stock data on international migration published by the United Nations. Four versions of the database are currently available and we choose to use the latest version of the database, given that its authors strived to correct for some biases specific to all stock data inferred from census data. The reference period is the 2000 round of population censuses. In order to get estimates of the total stock of migrants from each EECA country in 2000, we summed the stocks of migrants from the same origin country in all destination countries. This variable is denoted by $MIGRS$.

The database prepared by the Development Prospects Group of the World Bank is a variant of the Migration DRC database. The latter was updated using the most recent census data and unidentified migrants were allocated only to two broad categories, “other South” and “other North” (Ratha and Shaw, 2007). We used this database to get other estimates of the stocks of migrants from each EECA country in 2000. This variable is denoted by $MIGRWB$.

4.2.2 Two kinds of remittances data

The main sources of official data on migrants’ remittances are the annual balance of payments of various countries, which are compiled in the Balance of Payments Yearbook published annually.

---

14 See: www.migrationdrc.org/index.html
16 The Migration DRC methodology is available online at: www.migrationdrc.org/research/typesofmigration/global_migrant_origin_database.html. See Parsons et al., 2007 for more details.
by the International Monetary Fund (IMF). The IMF data include two categories of data: workers’ remittances including current transfers by migrants who are employed or intend to remain employed for more than a year in another economy in which they are considered residents, and workers’ remittances and compensation of employees made up of current transfers by migrant workers and wages and salaries earned by nonresident workers.

While the categories used by the IMF are well defined, there are several problems associated with their worldwide implementation that can affect their comparability. On the one hand, official remittance figures may underestimate the size of flows because they fail to capture informal remittance transfers, including sending cash back with returning migrants or by carrying cash and/or goods when migrants return home. Only two countries in EECA—Moldova and Russia—attempt to capture remittances sent through informal channels in the balance of payments statistics (World Bank, 2006). On the other hand, official remittance figures may also overestimate the size of the flows. Other types of monetary transfers—including illicit ones—cannot always be distinguished from remittances (Bilsborrow et al., 1997).

For the purpose of this study, we constructed two different variables from the WDI database: received workers’ remittances and compensation of employees (US$) and receipts of workers’ remittances (US$). In 2000, the first one, denoted by $REMCE$, was available for 25 EECA countries, while the second, denoted $REM$, was only available for 18 countries.\(^{17}\) In order to be able to compare these figures in the different countries, we first converted them into local currency units (LCU) using the official exchange rate of the WDI database and then used a PPP conversion factor.\(^{18}\) The WDI database offers two different PPP conversion factors: one for GDP and one for private consumption (i.e., household final consumption expenditure). Thus, we built four variables representing remittances in PPP: $REMCEPPP1$ and $REMPP1$ (using the PPP conversion factor for GDP), and $REMCEPPP2$ and $REMPPP2$ (using the PPP conversion factor for private consumption).

\(^{17}\) Data were missing for Belarus, Bulgaria, Czech Republic, Russian Federation, Serbia and Montenegro, Slovak Republic and Ukraine.

\(^{18}\) A PPP conversion factor is the number of units of a country’s currency required to buy the same amounts of goods and services in the domestic market as a U.S. dollar would buy in the United States.
4.2.3 Two assumptions about the investment rate of remittances

In this paper, we want to estimate the link between invested remittances and the number of equilibrium migrants. However, there is no information on the rate of investment of remittances sent by migrants. Thus, we made two different assumptions about the proportion of invested remittances.

According to the first hypothesis, invested remittances contribute to gross fixed capital formation (GFCF); the proportion of invested remittances out of total remittances is similar to the proportion of GFCF out of GDP. Thus, we build a first couple of variables, denoted by \( REMCEPPiGFCF \) and \( REMPPiGFCF \) (with \( i = 1, 2 \)), representing invested remittances in 2000 as the product of remittances and the share of GFCF in GDP, for each EECA country in the database (the cross-country average rate was of 21% in 2000).

According to the second hypothesis, we assume that migrants act in the same way as foreign investors; the proportion of invested remittances out of total remittances is then similar to the proportion of foreign direct investment (FDI) out of GDP. Thus, we build a second couple of variables, denoted by \( REMPPiCEFDI \) and \( REMPPiFDI \) (\( i = 1, 2 \)), representing invested remittances in 2000 as the product of remittances and the ratio of net inflows of FDI to GDP, for each EECA country in the database (the cross-country average rate was of 4.5% in 2000).

All the data come from the World Development Indicators (WDI) database.

4.2.4 Control variables

In our econometric model, we include as control variables either the GDP per capita (PPP) or the wage rate (PPP).

In the first case, we take GDP per capita as a proxy for the economic incentives to leave one’s origin country. Indeed, neoclassical economics stipulates that migration can be explained by the differential between anticipated wages in the origin and the potential host countries. But since we do not have information on bilateral remittances, we only use the level of GDP per capita in origin countries as a push factor potentially explaining migration. These data are taken from the WDI database and denoted by \( GDPcap \).
By the same token, in the second case, we use the wage rate in the origin country as a control variable. Wage rates data come from the International Labor Organization (ILO) where they can be found in LCU. Then, we built two variables representing wage rates in PPP: $WAGE_{PPP1}$ (using the PPP conversion factor for GDP) and $WAGE_{PPP2}$ (using the PPP conversion factor for private consumption).

### 4.2.5 Descriptive statistics

Descriptive statistics for the sample are shown in the following table:

</tr>
</tbody>
</table>

As can be seen, the two assumptions made about the rate of investment of remittances can be considered as a high hypothesis (when the rate of investment of remittances is proxied by the proportion of GFCF in GDP) and a low hypothesis (when the rate of investment of remittances is proxied by the proportion of FDI in GDP).

### 4.3 Empirical estimates

#### 4.3.1 The model

We want to analyze the equilibrium co-movements between invested remittances per migrant and the number of migrants. Proposition 3 claims that the two variables are positively correlated.

Thus, we postulate that the equilibrium number of migrants, $M$, (we can drop the star in this section), can be written as a function of invested remittances per migrants at the equilibrium, $\frac{IR}{M}$, a control variable, control, and an error term, $u$:

$$M = \beta_0 \left( \frac{IR}{M} \right)^{\beta_1} \text{control}^{\beta_2} u.$$  \hspace{1cm} (42)
Taking the log, we get:

\[
\ln(M) = b_0 + b_1 \ln(IR) + b_2 \ln(\text{control}) + \varepsilon, \quad (43)
\]

with \( b_0 = \frac{\ln(\beta_0)}{1+\beta_1}, \quad b_1 = \frac{\beta_1}{1+\beta_1}, \quad b_2 = \frac{\beta_2}{1+\beta_1}, \quad \varepsilon = \frac{\ln(u)}{1+\beta_1}. \)

All the coefficients of equation (42) can then be expressed as a function of the coefficients of equation (43):

\[
\begin{align*}
    b_0 &= \frac{\ln(\beta_0)}{1+\beta_1} \\
    b_1 &= \frac{\beta_1}{1+\beta_1} \quad \Leftrightarrow \quad \beta_0 = \exp\left(\frac{b_0}{1-b_1}\right) \\
    b_2 &= \frac{\beta_2}{1+\beta_1} \quad \Leftrightarrow \quad \beta_1 = \frac{b_1}{1-b_1} \\
    \varepsilon &= \frac{\ln(u)}{1+\beta_1} \quad \Leftrightarrow \quad \beta_2 = \frac{b_2}{1-b_1}
\end{align*}
\]

Thus, if we can estimate equation (43) and get estimates of \( b_0, b_1 \) and \( b_2 \), denoted by \( \hat{b}_0, \hat{b}_1 \) and \( \hat{b}_2 \), we can infer estimates of \( \beta_0, \beta_1 \) and \( \beta_2 \), denoted by \( \hat{\beta}_0, \hat{\beta}_1 \) and \( \hat{\beta}_2 \).

If our Proposition 3 is correct, the equilibrium number of migrants is positively related to the remitted amount per migrant. Thus, we expect \( \hat{\beta}_1 \) to be statistically greater than 0, which is true if \( \hat{b}_1 \) is statistically greater than 0 and smaller than 1. In addition, we expect the control variables, either GDP per capita or the wage in the origin country, to have a negative impact on the number of migrants; thus we expect \( \hat{\beta}_2 \) to be statistically negative.

4.3.2 Methodology and Results

In equation (43) the dependent variable is the number of migrants. As previously explained, the number of migrants can be taken either from the Global Migrant Origin Database or from the database prepared by the Development Prospects Group of the World Bank. Likewise, the main independent variable, invested remittances, can be measured either by workers’ remittances and compensation of employees or by workers’ remittances only, multiplied either by the gross fixed capital formation expressed as a percentage of GDP or by net inflows of foreign direct investment expressed as a percentage of GDP. Finally, the control variable can be either GDP per capita, or the wage rate measured with the PPP conversion factor either for GDP or for private consumption.
Hence, in a general form, the basic equation is:

\[
\ln \begin{bmatrix} MIGRWB \\ MIGRS \end{bmatrix} = b_0 + b_1 \ln \begin{bmatrix} REMCEPPPiGFCF \\ REMCEPPPiFDI \end{bmatrix} + b_2 \ln \begin{bmatrix} GDPcap \\ WAGEPPP1 \\ WAGEPPP2 \end{bmatrix} + \varepsilon. 
\]

\( (45) \)

- OLS estimates

In a first step, we use OLS to estimate various variants of this equation. The results of the regressions using the World Bank database for the stocks of migrants \( (MIGRWB) \) are as follows: \(^{19}\)

\(^{19}\) We obtain similar results with the dependant variable \( MIGRS \) (models 13 to 24).

**t**-student in brackets; *** significant to 1%; ** significant to 5%; * significant to 10%
In 9 models out of 12 the coefficient $\hat{b}_1$ is statistically positive and smaller than 1 at the 99% confidence level; it is always statistically positive and smaller than 1 at the 95% confidence level. The results corroborate Proposition 3. Furthermore, the estimates of $\hat{b}_1 \in [0.24; 0.63]$. This is tantamount to an elasticity of the equilibrium number of migrants with respect to remittances per migrant equal to $\beta_1 = \frac{\hat{b}_2}{1 - \hat{b}_1} \in [0.31; 1.7]$.

Concerning the coefficient $\hat{b}_2$, it is negative as expected and statistically significant in 6 models out of 12 at the 95% confidence level, and in all models but one at the 90% confidence level.

- Bootstrap estimations

In the previous regressions, the sample size varies from 12 to 24. This small sample size may raise difficulties determining confidence intervals of coefficients, since these intervals depend on assumptions on the distribution of the error term of the regression model. If these assumptions are no longer satisfied, standard confidence intervals can no longer be defined. We did test the normality assumption of the residuals in the different models using a Shapiro-Wilk test.\(^{20}\) in 5 models, the p-value is higher than 0.1, so we cannot reject the null hypothesis that the residuals are normally distributed; however, when the p-value is between 0.05 and 0.1 (in 4 models), we reject the null hypothesis at the 90% confidence level, and when it is between 0.01 and 0.05 (in 3 models), we reject the null hypothesis at the 95% confidence level. Thus, in some cases, the confidence intervals of these OLS coefficients may be wrong.

In order to improve the robustness of our estimations, we resort to the bootstrap method proposed by Efron (1979), which allows the approximation of an unknown distribution by an empirical distribution obtained by a resampling process. Bootstrap is a resampling technique based on random sorts with replacement in the data forming a sample. The application of bootstrap methods to regression models helps approximate the distribution of the coefficients (Freedman, 1981) and the distribution of the prediction errors when the regressors are data (Stine, 1985). Used to approximate the unknown distribution of a statistic by its empirical distribution, bootstrap methods are employed to improve the accuracy of statistical estimations (Juan and Lantz, 2001).

\(^{20}\) This is a suitable normality test for small samples.
Following Juan and Lantz (2001), we used a percentile-t bootstrap procedure, resampling the residuals. At the 95% confidence level, with 1000 resamples, we get the following results:

*: 90% confidence level interval: [0.16619; 0.96771]

As can be seen, the average coefficient (observed statistics) for both $\hat{b}_1$ and $\hat{b}_2$ are very much in line with OLS estimations. Most important, according to the bootstrap results, $\hat{b}_1$ is statistically positive and smaller than 1 (as claimed in Proposition 3) in 7 models out of 12 at the 95% confidence interval and in 10 models out of 12 at the 90% confidence interval. So this more rigorous method for determining confidence intervals does corroborate the OLS estimates.
4.3.3 Discussion

We tried to introduce other control variables to take into account institutional differences between EECA countries. However, a dummy variable differentiating East Europe countries from Central Asia countries is highly correlated with the GDP per capita (PPP) and the wage rate (PPP). Thus, it could not be introduced in the model. We also tried to take into account a possible lagged effect of invested remittances and used variables on the received amount of remittances one year earlier (in 1999). The results are quite similar to those presented and corroborate our proposition. Finally, we tried to introduce a "pull factor" variable representing the attractiveness of foreign countries for potential migrants, but important data were missing.

We acknowledge the fact that our empirical estimations should be subject to caution due to the modest quality of the data. In particular, data on migration and remittances do not take into account illegal migrants nor informal remittances. But since informal remittances are rarely invested and illegal migrants seldom use formal channel to remit, this measurement problem in the data may not be as serious as it seems. A more rigorous analysis would build on a more precise measure of the investment rate of remittances. Unfortunately, such data are not yet available.

5 Social optimum

In this paper, we analyze the optimality of migratory policies from the point of view of the developing country. A public planner may want to use policy levers to ensure that the equilibrium number of migrants is optimal according to a social welfare criterion. Indeed, the policymaker has an impact on both the migratory cost (by redefining the migratory policy or by helping potential migrants cover migratory costs) and the international transaction cost (by redesigning regulations and standards imposed to money transfer operators, by improving controls over informal money transfer channels or by improving competition in this sector).

21 Using received remittances in 1999 as the main dependent variable, we find that in 7 models out of 12, the OLS estimate of \( b_1 \) is statistically positive and smaller than 1 at the 99% confidence level; it is always statistically positive and smaller than 1 at the 95% confidence level. According to the bootstrap results, \( \hat{b}_1 \) is statistically positive and smaller than 1 in 9 models out of 12 at the 95% confidence interval and in all the models at the 90% confidence interval.

22 In this model, migration has no impact on the host country. Thus, we cannot define an optimal migratory policy from the viewpoint of the host country.
In order to study the optimal policy, we follow Schiff (2002) and assume that an "utilitarian" public planner seeks to maximize the total utility of the developing country citizens. The $M$ citizens of the developing country who migrated have a utility level $\ln V(M)$, while the $(L_0 - M)$ residents have a utility level $\ln W(M)$.

Thus, the objective of the social planner is to maximize the following total utility function:

$$U(M) = M \ln V(M) + (L_0 - M) \ln W(M)$$

Yet, at the migratory equilibrium, migrants' and residents' utilities are the same: $\ln V(M^*) = \ln W(M^*)$. Thus, at the equilibrium number of migrants $M^*$, total utility is:

$$U(M^*) = L_0 \ln W(M^*)$$

Then, in order for total utility to be maximized at the migratory equilibrium, residents' utility must be maximized. As we have seen in Section 3, residents' utility depends on the nature of the equilibrium.

**Proposition 5** There are three different cases:

- if $V_2 > W_1$, i.e. when migratory and transaction costs are too small, the optimal number of migrants and the equilibrium number are the same: everybody migrates (equilibrium 0);
- if $V_2 \leq W_1 < V_0$, the optimal number of migrants and the equilibrium number are the same: the developing country wage rate is maximized, there are between $M_1$ and $M_2$ migrants (equilibrium 1);
- if $V_0 \leq W_1$, i.e. when migratory and transaction costs are too high, the optimal number of migrants and the equilibrium number coincide if and only if the equilibrium number of migrants is $M_1$, i.e. if $V_0 = W_1$. Else, migration is insufficient and does not maximize the total utility of the citizens of the developing country at the equilibrium (equilibrium 2).

Thus, optimum and equilibrium can coincide only in two specific cases: either all the population of the developing country migrates, or the number of migrants maximizes the developing country wage. In the opposite case, migration is insufficient and does not maximize the total utility of the developing country citizens.

---

23 Alternatively, the public planner could seek to maximize total output in the developing country; it would lead us to similar conclusions.
Studying only the most interesting equilibrium (Equilibrium 2), the condition $V_0 = W_1$ yields the optimal migratory cost as a function of fixed and variable transaction costs: $c_{opt} = c(\alpha, \beta)$.

$$c_{opt}(\alpha, \beta) = s - \frac{\beta}{\alpha} \left( \frac{1}{1 + \frac{1}{r}} \right)^{\frac{1}{\alpha^2}} \left( \frac{1}{1 + \frac{1}{r}} \right)^{\frac{1}{\alpha^2}} (1 - a) A R \left( \frac{a}{r} \right)^{\alpha^2} .$$

(48)

An intuitive approach can be provided by means of a numerical simulation of this function.

Figure 4 represents the optimal migratory cost with respect to the variable cost $(1 - \alpha)$ for different values of the fixed cost $\beta$.

Thus, the optimal migratory cost turns out to be a decreasing function of transaction costs (either fixed or variable). Indeed, if for given transaction costs the migratory cost is "too big", the equilibrium number of migrants is too small.

6 Conclusion

This paper examines the existence and properties of a steady migratory equilibrium, and the public policies that should be implemented to make this migratory equilibrium optimal. We develop a simple two-country migratory model, where the incentives to migrate are explained by the differential between wages in the two countries and where migrants’ remittances are invested in capital formation in the origin country. Migrants are assumed to be egoist, they migrate and

---

24 If we also take into account equilibrium 1, we find:

$$V_0 \leq W_1 \leq V_0 \iff s - (1 - a) A R \left( \frac{a}{r} \right)^{\alpha^2} \leq c_{opt}(\alpha, \beta) \leq s - \frac{\beta}{\alpha} \left( \frac{1}{1 + \frac{1}{r}} \right)^{\frac{1}{\alpha^2}} \left( \frac{1}{1 + \frac{1}{r}} \right)^{\frac{1}{\alpha^2}} (1 - a) A R \left( \frac{a}{r} \right)^{\alpha^2} .$$

25 Here, we chose: $\rho = 0.03$, $r = 0.03$, $a = 0.3$, $A = 10$, and $s = 20$ : $\beta$ varies between 1 and 5.
invest at home in order to maximize their own utility, yet their egoism is beneficial to the left-home labor force.

Because of a joint effect of migration which leads to a decrease in the labor supply of the developing country, and of the investment of remittances which induces an increase in the capital stock of the developing country, the per worker income of this country first increases with the number of migrants, then stay constant at his maximum level, then is discontinuous: it suddenly decreases, to increase again until it reaches its maximum, and finally decreases until it reaches zero.

A migratory equilibrium is reached when the marginal citizen of the developing country is indifferent between migrating and remaining, i.e. when migrants and residents have the same utility level. We then show that there exists four types of migratory equilibria: everyone migrates (when the net migratory benefit is too high); nobody migrates (in the opposite case and/or when transaction costs are too high); the equilibrium number of migrants is below the number of migrants maximizing the developing country wage rate (when the utility in case of migration is lower than the utility of a resident getting paid the maximum wage); finally, there exists one or two steady equilibrium above this threshold.

Studying more in depth the steady equilibrium expected to prevail for the broadest range of parameter values, we show that the higher the wage in the host country and the lower the migratory cost, the higher the remittances and the equilibrium migration rate. It turns out that the optimal remitted amount per migrant and the equilibrium number of migrants move in the same direction in response to various shocks. We test for this implication of our model using EECA data from 2000. OLS and bootstrap estimates put forward a positive elasticity of the number of migrants with respect to remittances per migrant, in the range of \([0.31; 1.7]\), keeping in line with the theoretical model. For sure, these figures should be interpreted cautiously, given the modest quality of the data on migrations and remittances.

This model enables us to draw off some lessons as regards public policies. Indeed, policies can impact the equilibrium number of migrants through their effect on migratory and international transaction costs. Migratory policy can more or less ease the migration process and thus has an
influence on individual migration costs. In addition, regulations, standards and controls regarding international transfers of funds have an impact on international transaction costs and thus on remitted amounts. In the equilibrium under scrutiny in this paper, the number of migrants is in general sub-optimal. We thus analyze how a utilitarian policymaker should manipulate migratory and transaction costs such as to push up the number of migrants, and indirectly, the wage of the residents.

The model is based on several assumptions, and some of them are simplifying. First of all, we assume that the arrival of immigrants does not have an impact on the host country wage rate. This assumption is related to the lack of consensus in the literature on the impact of migrants on the host country wage rate. If this assumption were loosened, the remitted amount would always depend on the number of migrants, and the migratory equilibria would be modified. The optimal migratory policy should also take into account the impact of migration on the host country, and a bargaining mechanism should be introduced to work out the equilibria outcome. We also assumed that residents cannot invest in their own country. In the opposite case, a resident could invest an amount increasing with his wage and the supply of capital in the developing country would increase more quickly than in the analyzed case. A single steady migratory equilibrium would still exist (under certain conditions), but optima would be different. Finally, it could be interesting to carry on with this study by differentiating workers according to their skills, acknowledging the fact that their propensity to remit depends on their skills (Faini, 2007), and by taking into account the possible impact of migrant workers on technology through the improvement in social capital (Docquier and Rapoport, 2009).

The model is too simple to claim at providing an exhaustive view on recent migratory trends. His limited but original contribution to existing literature is to point out the role of invested remittances in capital formation in developing countries, which, when coupled with a shrinking labor supply, brings about an offsetting impact on the very first motive to migrate: the weakness of wages in the developing world.

A Appendix

A.1 Migrants remittances

A.1.1 Conditions for strictly positive remittances

A migrant will remit a strictly positive optimal amount if his utility with investment is higher than his utility with no investment.

Formally:
\[ V_0 > V_2 \iff (\alpha (1 + r))^{\frac{1}{1+r}} - 1 > (s - c) > (1 + r) \frac{\beta}{\alpha} \]

First of all, the following condition must be met: \( \alpha (1 + r) > 1 \). Then, we need: \( (s - c) > \frac{\alpha (1 + r)}{\alpha (1 + r) - 1} \frac{\beta}{\alpha} \).

We assume that these two conditions are met all along the paper.

A.1.2 When do migrants stop investing in their origin country?

When the previous conditions are met, migrants invest their optimal amount in their origin country as long as there are less than \( M_1 \) migrants. When migration is above \( M_1 \), migrants’ investments are limited and their indirect utility decreases. We can then wonder when investing becomes less attractive than not investing. Let’s denote \( M_2 \) this threshold.

Here, we study the case when there are more than \( M_1 \) migrants. Remittances per migrant are then limited to \( R_1 (M) \), decreasing with \( M \). Migrants stop investing in their origin country when their utility without investment \( (V_2) \) becomes higher than their utility with investment \( (V_1 (M)) \).

Formally, \( R_1 (M_2) = 0 \iff V_1 (M_2) = V_2 \iff -V_1 (M_2) + V_2 = 0. \)

Let’s denote \( X = R_1 (M) \) \( \approx \frac{1}{R_0 \alpha} \in \left[ 0 ; (R_0 \alpha)^{\frac{1}{1+r}} \right]. \)

We want to solve:
\[ F (X) = 0, \quad \text{with} \quad F (X) = \frac{(1 + r)^{\frac{1}{1+r}}}{\alpha} X^{2 + \rho} - \frac{(1 + r)^{\frac{1}{1+r}}}{\alpha} (2 + \rho) R_0 X + (1 + \rho) \left( \frac{s - c}{2 + \rho} \right)^{\frac{2 + \rho}{1+r}}. \]

\( F (X) \) decreases over \( \left[ 0 ; (R_0 \alpha)^{\frac{1}{1+r}} \right] \), from \( V_2 > 0 \) to \( V_2 - V_0 < 0 \).

Thus, there exists a single \( X_0 \in \left[ 0 ; (R_0 \alpha)^{\frac{1}{1+r}} \right] \) such that \( F (X_0) = 0. \)

In other words, there exists a single \( M_2 > M_1 \) such that \( \forall M \geq M_2, V_1 (M) \leq V_2. \) When \( M \geq M_2 \), migrants do not invest anymore.
In addition:

\[ V_1(M) = 0 \iff M = L_0 - \left( \frac{r}{aA} \right)^{\frac{1}{r-\alpha}} K_0 \]

We infer: \( M_2 < L_0 - \left( \frac{r}{aA} \right)^{\frac{1}{r-\alpha}} K_0 \) and \( k(M_2) < \left( \frac{aA}{r} \right)^{\frac{1}{r-\alpha}} \).

### A.2 The developing country wage

Proof of Proposition 1.

- **1\textsuperscript{st} case:** \( M \leq M_1 \)

  Differencing the wage rate with respect to the number of migrants, we get:

  \[
  \frac{dw(M)}{dM} = \left[ aA [k(M)]^{a-1} - r \right] \frac{K_0 + L_0 R}{(L_0 - M)^2}.
  \]

  Note that:

  \[
  \frac{dw(M)}{dM} \geq 0 \iff k(M) \leq k(M_1) = \left( \frac{aA}{r} \right)^{\frac{1}{r-\alpha}} \text{ or } M \leq M_1 = \frac{L_0 - \left( \frac{r}{aA} \right)^{\frac{1}{r-\alpha}} K_0}{1 + \left( \frac{r}{aA} \right)^{\frac{1}{r-\alpha}} R}.
  \]

  The wage rate is an increasing function of \( M \) over \([0; M_1]\). It reaches its maximum when migration reaches \( M_1 \); its maximum level is \( w(M_1) = (1 - a) A \left( \frac{aA}{r} \right)^{\frac{1}{r-\alpha}} > w_0 > 0 \).

- **2\textsuperscript{nd} case:** \( M_1 < M \leq M_2 \)

  When the number of migrants is between \( M_1 \) and \( M_2 \), migrants each remit \( R_1(M) \) such that the capital intensity in the developing country is \( \left( \frac{aA}{r} \right)^{\frac{1}{r-\alpha}} \). The wage rate in the developing country is constant and equal to \( w(M_1) \) (equation 26).

- **3\textsuperscript{rd} case:** \( M_2 < M < L_0 \)

  When the number of migrants is between \( M_2 \) and \( L_0 \), migrants do not invest in their origin country. The wage rate thus becomes: \( w(M) = A \left[ \frac{K_0}{L_0 - M} \right]^a - r \left[ \frac{K_0}{L_0 - M} \right] \).

  Differencing this expression with respect to the number of migrants, we get:

  \[
  \frac{dw(M)}{dM} = \frac{1}{L_0 - M} \left[ \frac{K_0}{L_0 - M} \right]^a \left\{ aA - r \left[ \frac{K_0}{L_0 - M} \right]^{1-a} \right\}.
  \]

  Note that:

  \[
  \frac{dw(M)}{dM} \geq 0 \iff M \leq M_3 = L_0 - \left( \frac{r}{aA} \right)^{\frac{1}{r-\alpha}} K_0.
  \]
The wage rate in the developing country is then a function increasing with the number of migrants over \([M_2; M_3]\) and decreasing over \([M_3; L_0]\). It reaches its maximum value over this interval in \(M_3\); it is then equal to \(w(M_3) = (1 - a) \frac{K_0}{L_0 - M_1} A^{\frac{1}{1 - a}} \). In addition, note that:

\[
\lim_{M \to L_0} w(M) = \lim_{M \to L_0} \left[ A \left( \frac{L_0 - M}{K_0} \right)^{1 - a} - r \right] = -\infty.
\]

Thus, there is a number of migrants \(M_4\) such that when migration reaches that threshold, the wage rate is null:

\[
w(M_4) = 0 \iff M_4 = L_0 - \left( \frac{r}{A} \right)^{\frac{1}{1 - a}} K_0.
\]

### A.3 The equilibrium number of migrants

Proof of Proposition 2.

1\textsuperscript{st} case: \(M \in [0; M_1]\)

Then migrants’ utility is \(V_0\) and residents’ utility is increasing with the number of migrants from \(W_0 = W_0(M = 0)\) to \(W_1\). There is an equilibrium number of migrants \(M^* \in [0; M_1]\) such that \(W_0(M^*) = V_0\) if and only if \(V_0 \in [W_0; W(M_1)]\). When it exists, \(M^*\) is a steady equilibrium:

Pretend that migration is at the level \(M^* - dM\). Then \(W_0(M^* - dM) < W_0(M^*) = V_0\) and \(W_0(M)\) is increasing in \(M\). Residents prefer to migrate whereas migrants do not want to come back. Step by step, the number of migrants increases, residents’ utility increases until it reaches \(W_0(M^*)\), right when migration reaches \(M^*\).

Pretend that migration is at the level \(M^* + dM\). Then \(W_0(M^* + dM) > W_0(M^*) = V_0\) and \(W_0(M)\) is increasing in \(M\). Residents prefer to remain whereas migrants prefer to come back. Step by step, the number of migrants decreases, residents’ utility decreases until it reaches \(W_0(M^*)\), right when migration reaches \(M^*\).

2\textsuperscript{nd} case: \(M \in [M_1; M_2]\)

Then residents’ utility is \(W_1\) and migrants’ utility is \(V_1(M)\), decreasing from \(V_0\) to \(V_2\). There is an equilibrium number of migrants \(M_1^* \in [M_1; M_2]\) such that \(V_1(M_1^*) = W_1\) if and only if \(W_1 \in [V_2; V_0]\). \(M_1^*\) is a steady equilibrium.

3\textsuperscript{rd} case: \(M \in [M_2; M_3]\)
Then migrants’ utility is $V_2$ and residents’ utility is increasing with the number of migrants from $W_2(M_2)$ to $W_1$. There is an equilibrium number of migrants $M_2^* \in [M_2; M_3]$ such that $W_2(M_2^*) = V_2$ if and only if $V_2 \in [W_2(M_2); W_1]$. $M_2^*$ is a steady equilibrium.

4th case: $M \in ]M_3; M_4]$  

Then migrants’ utility is $V_2$ and residents’ utility is decreasing with the number of migrants from $W_1$ to 0. There is an equilibrium number of migrants $M_3^* \in ]M_3; M_4]$ such that $W_2(M_3^*) = V_2$ if and only if $V_2 \in [0; W_1]$. $M_3^*$ is not a steady equilibrium.

A.4 Characteristics of Equilibrium 2  
A.4.1 Proof of Proposition 3.

According to the definition of the capital intensity (3), we know that: $k^* = \frac{K_0 + M^* R_0}{L_0 + M^*} \iff M^* = \frac{\frac{L_0 k^* - K_0}{R_0 + k^*}}{\frac{L_0}{R_0} + k^*} \in [0; M_1]$.

Differentiating with respect to $R_0$, we get:

$$\frac{\partial M^*}{\partial R_0} = \frac{1}{(R_0 + k^*)^2} \left[ K_0 \left( 1 + \frac{\partial k^*}{\partial R_0} \right) + L_0 \left( R_0 \frac{\partial k^*}{\partial R_0} - k^* \right) \right].$$

Thus, we need to determine the sign of $\left( 1 + \frac{\partial k^*}{\partial R_0} \right)$ and $\left( R_0 \frac{\partial k^*}{\partial R_0} - k^* \right)$.

First step, according to the definition of $M^*$, we know:

$$W_0(M^*) = V_0 \iff A(k^*)^\alpha - r k^* = (2 + \rho) \left( \frac{1}{\alpha} \right)^{\frac{1 + \rho}{1 + \rho}} (1 + r)^{\frac{1}{1 + \rho}} R_0.$$  \hspace{1cm} (49)

Differentiating with respect to $R_0$:

$$\left( a A(k^*)^{\alpha - 1} - r \right) \frac{\partial k^*}{\partial R_0} = (2 + \rho) \left( \frac{1}{\alpha} \right)^{\frac{1 + \rho}{1 + \rho}} (1 + r)^{\frac{1}{1 + \rho}}$$

$$\frac{\partial k^*}{\partial R_0} = (2 + \rho) \left( \frac{1}{\alpha} \right)^{\frac{1 + \rho}{1 + \rho}} (1 + r)^{\frac{1}{1 + \rho}} \frac{1}{a A(k^*)^{\alpha - 1} - r}.$$

Since the marginal productivity of capital is higher than the interest rate $(a A(k^*)^{\alpha - 1} - r > 0)$, we infer: $\frac{\partial k^*}{\partial R_0} > 0$ and $1 + \frac{\partial k^*}{\partial R_0} > 0$. 

45
Second step,

\[
R_k \frac{\partial k}{\partial R} - k = \frac{k^*}{aA(k^*)^\alpha - rk^*} \left[ \left( \frac{1 + \alpha}{\alpha} \right)^{\frac{\alpha}{1 + \alpha}} (1 + r)^{\frac{1}{1 + \alpha}} - \frac{R_0}{(aA(k^*)^\alpha - rk^*)} \right]
\]

\[
R_k \frac{\partial k}{\partial R} - k = \frac{k^*}{aA(k^*)^\alpha - rk^*} [(A(k^*)^a - rk^*) - (aA(k^*)^\alpha - rk^*)] \text{ according to eq. (49)}
\]

\[
R_k \frac{\partial k}{\partial R} - k = (1 - a) \frac{A(k^*)^{1+a}}{aA(k^*)^\alpha - rk^*} > 0 \text{ since } a < 1.
\]

Thus \(1 + \frac{\partial k}{\partial R} \) and \(R_k \frac{\partial k}{\partial R} - k^* \) are positive. We can conclude that:

\[
\frac{\partial M}{\partial R} > 0.
\]

Thus optimal remittances per worker and the equilibrium number of migrants are positively related.

**A.4.2 Proof of Proposition 4.**

To prove that the equilibrium number of migrants is an increasing function of the net migratory benefit \((s - c)\), and a decreasing function of the fixed transaction costs, we follow the same type of reasoning.

To prove the last part of the proposition (if \(a \leq \frac{1}{2 \gamma \rho}\), the smaller the variable transaction costs, the higher the equilibrium migration), we follow the same kind of reasoning. First, we show that \(\frac{\partial k}{\partial \alpha} + \frac{\partial R}{\partial \alpha} > 0\). Then we get:

\[
R_k \frac{\partial k}{\partial \alpha} - k \frac{\partial R}{\partial \alpha} = \frac{k^*}{aA(k^*)^\alpha - rk^*} \left\{ \left( \frac{1}{\alpha} \right)^{\frac{\alpha}{1 + \alpha}} (1 + r)^{\frac{1}{1 + \alpha}} \left[ (s - c) (R_0) (1 - (2 + \rho) a) + (1 + \rho) R_0 \frac{R}{a} \right] \right\}
\]

\[
+ (s - c) (1 - a) rk^*
\]

Thus, if \(a \leq \frac{1}{2 \gamma \rho}\), then \(R_k \frac{\partial k}{\partial \alpha} - k \frac{\partial R}{\partial \alpha} \geq 0\) and \(\frac{\partial M}{\partial \alpha} > 0\).
