Abstract:
In this paper, we propose a variance reduction method for quantile regressions with endogeneity problems. First, we derive the asymptotic distribution of two-stage quantile estimators based on the fitted-value approach under very general conditions on both error terms and exogenous variables. Second, we exhibit a bias transmission property derived from the asymptotic representation of our estimator. Third, using a reformulation of the dependent variable, we improve the efficiency of the two-stage quantile estimators by exploiting a trade-off between an asymptotic bias confined to the intercept estimator and a reduction of the variance of the slope estimator. Monte Carlo simulation results show the excellent performance of our approach. In particular, by combining quantile regressions with first-stage trimmed least-squares estimators, we obtain more accurate slope estimates than 2SLS, 2SLAD and other estimators for a broad range of distributions.

Key words: Two-Stage Estimation, Variance Reduction, Quantile Regression, Asymptotic Bias.

JEL codes: C13, C30.

1 Introduction

This paper considers the estimation of a structural equation using quantile regression. Since the seminal work by Koenker and Bassett (1978), the literature on quantile regression has grown rapidly. There are two strands in the literature about quantile regression in the presence of endogeneity. The first one, which we call the ‘structural approach,’ corresponds to models specified in terms of the conditional quantile function of the structural equation and usually allows for heterogeneous (or non-constant) quantile treatment effects through nonseparable models. On the other hand, the second one, which we refer to as the ‘fitted-value approach,’ is based on the conditional quantile function of the reduced-from equation. In the latter approach, the analysts substitute the endogenous regressors with their fitted values obtained from some auxiliary regression based on other exogenous variables. We follow the latter approach in this paper. For quantile regressions, it is anchored on conditional quantile restrictions applied to the reduced-form equation.

Owing to its computational convenience, the fitted-value approach has been used to estimate homogeneous (or constant) quantile treatment effects. The theoretical foundation for the fitted-value approach was first laid by Amemiya (1982) and Powell (1983) who analyze the two-stage least-absolute-deviations estimator in a simple setting. Chen (1988) and Chen and Portnoy (1996) investigate two-stage quantile regression in which the trimmed least squares (TLS) and least absolute deviations (LAD) estimators are employed as the first-stage estimators, assuming that the error terms are independent and identically distributed (IID). Kim and Muller (2004) use a similar approach with quantile regression in the first stage. Although the fitted-value approach has sometimes been used in applied work in which data are affected by serial correlation and heteroskedasticity, no theoretical results under such general conditions have been provided.

In this paper, we make several contributions to the literature on the fitted-value approach. First, we derive the asymptotic distribution and the variance-covariance matrix of the two-stage quantile estimator under very general conditions on both error terms and explanatory variables. Second, we exhibit a ‘bias transmission property’ that characterizes the asymptotic representation of our estimator. We use this property to facilitate the analyses of the link of reduced-form and structural model, and to confine estimation bias on the intercept for some models. Third, we propose a new method to improve the efficiency of the two-stage quantile regressions. This method is based on an idea in Amemiya (1982), who uses a composite dependent variable that is a weighted combination of the original dependent variable and its fitted value. This composite dependent variable is used in the second stage and the combination weight is varied to reduce the variance of the two-stage quantile estimator.

A well-known method to reduce the variance of an estimator in statistics is to combine the estimator with either a fixed point or another estimator, which creates the trade-off between bias and efficiency. In this case, the optimal combination weight is determined by minimizing the asymptotic variance of the combination estimator. This approach is difficult to apply to two-stage estimation because it generally either makes the entire estimator biased or requires the estimation of the joint distribution of the two combined estimators. In contrast, our approach of using a composite dependent variable implies that (i) only the intercept estimator is inconsistent with the consistency of the slope estimator not depending on the weight parameter, and (ii) the variance

---

2. For example, Arias et al. (2001), Garcia et al. (2001), Chevapatrakul et al. (2009) and Chortareas et al. (2012).

3. For example, see James and Stein (1960), Sen and Saleh (1987), and Kim and White (2001).
of the consistent slope estimator can be reduced by adjusting the weight parameter. The results of our Monte Carlo simulations show that considerable efficiency gains can be achieved by using the proposed variance reduction method. This is particularly noticeable when compared to typical estimators such as 2SLS or 2SLAD.

The paper is organized as follows. Section 2 discusses the model and the assumptions. In Section 3, we derive the asymptotic representation of the two-stage quantile regression estimator. We characterize the asymptotic bias of general two-stage estimators in Section 4. We analyze in Section 5 the asymptotic normality and the asymptotic covariance matrix of two-stage quantile estimators based on LS or TLS predictions. We also investigate the optimal weights that minimize the asymptotic variance of two-stage quantile estimators. In Section 6, we present Monte Carlo simulation results. Finally, Section 7 concludes. All technical proofs are collected in Appendix A.

2 The Model

We are interested in estimating the parameter \((\alpha_0)\) in the following structural equation by quantile regression:

\[
y_t = x_t' \beta_0 + Y_t' \gamma_0 + u_t = z_t' \alpha_0 + u_t,
\]

where \([y_t, Y_t']\) is a \((G + 1)\) row vector of endogenous variables, \(x_t'\) is a \(K_1\) row vector of exogenous variables, \(z_t = [x_t', Y_t']\), \(\alpha_0 = [\beta_0', \gamma_0']\) and \(u_t\) is an error term. We denote by \(x_{0t}^2\) the row vector of the \(K_2\) exogenous variables excluded from (1).

By assumption, the first element of \(x_t\) is 1. This crucial assumption will allow us to confine a bias to an intercept parameter, often less interesting for analysts than the slope coefficients. We further assume that \(Y_t\) can be linearly predicted from all of the exogenous variables:

\[
Y_t' = x_t' \Pi_0 + V_t',
\]

where \(x_t' = [x_{1t}', x_{2t}']\) is a \(K\) row vector with \(K = K_1 + K_2\), \(\Pi_0\) is a \(K \times G\) matrix of unknown parameters and \(V_t'\) is a \(G\) row vector of unknown error terms.

Using (1) and (2), \(y_t\) can also be expressed as follows:

\[
y_t = x_t' \pi_0 + v_t,
\]

where

\[
\pi_0 = H(\Pi_0) \alpha_0 \text{ with } H(\Pi_0) = \begin{bmatrix} I_{K_1} \\ 0 \end{bmatrix}, \Pi_0
\]

and \(v_t = u_t + V_t' \gamma_0\).

Equations (2) and (3) are the basis of the first-stage estimation that yields estimators \(\hat{\pi}_t\) and \(\hat{\Pi}_0\). So far, we did not mention any restriction on errors. The precise error restrictions will be introduced below in Assumptions 3 and 4 when dealing with examples of first-stage estimators. This is because we wish to keep the framework as general as possible until we deal with these examples. However, to set ideas, the reader may wish to consider conditional quantile restriction on \(v_t\) in the fitted-value approach. We now specify the data generating process.

\footnote{Using another coefficient of secondary interest is possible for our argument, while it makes the presentation more interesting by choosing the intercept.}
The sequence \( \{(x'_t, u_t, v_t)\} \) is \( \alpha \)-mixing with mixing numbers \( \{\alpha(s)\} \) of size \(-2(4K + 1)(K + 1)\).\(^5\)

Studying quantile regressions with \( \alpha \)-mixing processes is an unusual degree of generality. One step in this direction was made by Portnoy (1991), who derived asymptotic results of quantile estimators in dependent and even non-stationary cases, using \( m(n) \)-decomposability of random variables.

It is generally possible to employ unbiased estimators in the first stage. However, in order to exploit later on a trade-off between bias and efficiency, we allow in Assumption 2 for inconsistent first-stage estimation with bounded asymptotic bias terms in the following assumption. This form is convenient for including the contribution of first-stage estimators in the asymptotic distribution of our final estimator. The precise restrictions on \( v_t \) and \( V_t \) corresponding to \( \pi_0 \) and \( \Pi_0 \) will be brought up later on.

**Assumption 2.** There exist finite bias vectors \( B_\pi \) and \( B_\Pi \) such that
\[
T^{1/2}(\hat{\pi} - \pi_0 - B_\pi) = O_p(1) \quad \text{and} \quad T^{1/2}(\hat{\Pi} - \Pi_0 - B_\Pi) = O_p(1).
\]

When the bias terms \( B_\pi \) and \( B_\Pi \) are zero, the first-stage estimators are consistent. A case of non-zero bias terms is when the reduced form equation in (3) is estimated by LS to produce the first-stage estimator \( \hat{\pi} \), whereas the usual conditional quantile restriction (i.e. the zero quantile restriction) is placed on \( v_t \) in the same equation. In that case, the zero mean restriction on \( v_t \) cannot be simultaneously satisfied in general. This implies that the intercept estimator, at least in \( \hat{\pi} \), is inconsistent.

Let us now say more about two-stage quantile regressions in our setting. For any quantile \( \theta \in (0, 1) \), we define \( \rho_\theta(z) = z\psi_\theta(z) \), where \( \psi_\theta(z) = \theta - 1_{\{z \leq 0\}} \) and \( 1_{\{\cdot\}} \) is the indicator function. If the orthogonality conditions, \( E(z_t\psi_\theta(u_t)) = 0 \), were satisfied, then the usual one-stage quantile regression estimator (QR) would be consistent. However, when \( u_t \) and \( Y_t \) (a sub-vector of \( z_t \)) are statistically linked under weak endogeneity of \( Y_t \), these conditions may not be satisfied. In that case, the QR of \( \alpha_0 \) is generally not consistent, which is the endogeneity problem that prevents us from using simple quantile regressions.

As an extension of Amemiya (1982), Powell (1983) and Chen and Portnoy (1996) to broader DGP’s, we define, for any quantile \( \theta \), the Two-Stage Quantile Regression (2SQR(\( \theta, q \))) estimator \( \hat{\alpha} \) of \( \alpha_0 \) as a solution to the following program:
\[
\min_\alpha \quad S_T(\alpha, \hat{\pi}, \hat{\Pi}, q, \theta) = \sum_{t=1}^T \rho_\theta(qy_t + (1 - q)\hat{y}_t - x'_tH(\hat{\Pi})\alpha),
\]
where \( \hat{y}_t = x'_t\hat{\pi} \), \( q \) is a positive scalar constant, and \( \hat{\pi}, \hat{\Pi} \) are first-stage estimators. In the quantile regression in (5), the dependent variable \( qy_t + (1 - q)\hat{y}_t \) is a weighted average of \( y_t \) and of its fitted-value \( \hat{y}_t \) obtained from the reduced form equation in (3). The combination weight \( q \) is restricted to be positive for a technical reason discussed in the proof of Proposition 1 below. Alternatively, as in Powell (1983), the case \( q \) negative is also possible by imposing \( \theta = 0.5 \), i.e., with the LAD estimator.

The reformulation of the dependent variable as \( qy_t + (1 - q)\hat{y}_t \) was originally suggested by Amemiya (1982) to improve efficiency in two-stage estimation with \( 0 < q < 1 \). The case \( q = 0.5 \) was originally suggested by Amemiya (1982) to improve efficiency in two-stage estimation with \( 0 < q < 1 \). The case \( q = 0.5 \) was originally suggested by Amemiya (1982) to improve efficiency in two-stage estimation with \( 0 < q < 1 \). The case \( q = 0.5 \) was originally suggested by Amemiya (1982) to improve efficiency in two-stage estimation with \( 0 < q < 1 \).
1 corresponds to the usual two-stage quantile regression estimator, while \( q = 0 \) corresponds to the inverse regression estimator under exact identification. Thus, the new dependent variable introduces a trade-off between two estimation methods. To obtain the asymptotic distribution of the 2SQR(\( \theta, q \)) estimator, we impose the following usual regularity conditions.

**Assumption 3.** (i) \( H(\Pi_0 + B_{\Pi}) \) is of full column rank.
(ii) Let \( F_t(\cdot|x) \) be the conditional cumulative distribution function (CDF) and \( f_t(\cdot|x) \) be the conditional probability density function (PDF) of \( v_t \). The conditional PDF \( f_t(\cdot|x) \) is assumed to be Lipschitz continuous for all \( x \), strictly positive and bounded by a constant \( f_0 \) (i.e., \( f_t(\cdot|x) < f_0 \), for all \( x \)).
(iii) The matrices \( Q = \lim_{T \to \infty} E \left[ \frac{1}{T} \sum_{t=1}^{T} x_t x_t' \right] \) and \( Q_0 = \lim_{T \to \infty} E \left[ \frac{1}{T} \sum_{t=1}^{T} f_t(0|x_t)x_t x_t' \right] \) are finite and positive definite.
(iv) \( E(\psi_{\theta}(v_t)|x_t) = 0 \), for an arbitrary \( \theta \).
(v) There exists a positive number \( C > 0 \) such that \( E(\|x_t\|^3) < C < \infty \) for any \( t \).

Assumption 3(i) is analogous to the usual identification condition for simultaneous equations models. The bias \( B_{\Pi} \) appears in the condition because the first-stage estimator converges towards \( \Pi_0 + B_{\Pi} \). In the case when OLS is used for estimating \( \Pi_0 \), Assumption 3(i) ensures that \( E[x_t y_t] \neq 0 \). It implies similar conditions when other estimators are used. Assumption 3(ii) simplifies the demonstration of convergence of remainder terms to zero for the calculation of the asymptotic representation. The second part of Assumption 3(iii) is the counterpart of the usual condition for OLS that the sample second moment matrix of the regressor vectors converges towards a finite positive definite matrix, which corresponds to the first part. The last condition is akin to the one in the conventional IV approach in that this condition is necessary for consistency and for the inversion of the relevant empirical process to establish the asymptotic normality.

Assumption 3(iv) is the assumption that zero is the given \( \theta^{th} \)-quantile of the conditional distribution of \( v_t \). It identifies the coefficients of the model. Assumption 3(v), the moment condition on the exogenous variables, is necessary for the stochastic equicontinuity of our empirical process in the dependent case, which is used for the asymptotic representation. We also use it to bound the asymptotic covariance matrix of the parameter estimators. The conditions on the exogenous regressors are weaker than what is usually employed in the two-stage quantile regression literature.

Assumption 3(iv) is central to our fitted-value approach. The conditional quantile restriction is placed on the reduced-form error \( v_t \) and the information set used for the conditional restriction exclusively consists of exogenous variables \( x_t \). It has been used in simpler settings in Amemiya (1982), Powell (1981), Chen and Portnoy (1998) and Kim and Muller (2004).

Given that \( v_t \) is a function of the structural error \( u_t \) and the prediction equation error \( V_t \), it may be difficult to interpret the quantile restriction in Assumption 3(iv) and to provide good examples in which such a restriction holds. One condition to make Assumption 3(iv) plausible and easy to interpret is the quantile-independence condition: \( E(\psi_{\theta}(v_t)|x_t) = E(\psi_{\theta}(v_t)) \). Under the quantile-independence condition, only constant quantile treatment effect models can be specified and estimated. In that case, the intercept estimates describe the parallel shifts in the unconditional quantiles of the error term.

Despite being limited to constant quantile treatment effect models, the fitted-value approach

\(^6\)In the iid case, the term \( f(F^{-1}(\theta))^{-1} \) typically appears in the variance formula of a quantile estimator (Koenker and Bassett, 1978). However, due to Assumption 3(iv), \( F^{-1}(\theta) \) is now zero so that we have \( f(0)^{-1} \) instead, in this case.
has several advantages worth mentioning. First, it does not involve any computational problem, even with a large number of endogenous and exogenous variables, whereas the structural approach cannot handle such a case. For example, the grid search method in Chernozhukov and Hansen (2006) becomes increasingly difficult to implement as the number of endogenous variables increases. Second, considering the fitted-value approach allows us to propose a new powerful method of variance reduction. We now study the asymptotic properties of 2SQR(θ, q) in the next section.

3 The Asymptotic Representation

To derive the asymptotic representation of the 2SQR(θ, q) estimator, we define the following empirical process.

\[ M_T(\Delta) = T^{-1/2} \sum_{t=1}^{T} x_t \psi_\theta(q v_t - T^{-1/2} x_t' \Delta), \]

where \( \Delta \) is a \( K \times 1 \) vector. Applying Theorem II.8 in Andrews (1990) yields the following lemma. The lemma is proven only for the quantile regression case, while similar derivations can be done for other two-stage M-estimators.

Lemma 1. Suppose that Assumptions 1 and 3 hold. Then, for any \( L > 0 \), we have the following result:

\[ \sup_{||\Delta|| \leq L} ||M_T(\Delta) - M_T(0) + q^{-1} Q_0 \Delta|| = o_p(1). \]

Combining Lemma 1 and Assumption 2 allows us to obtain the asymptotic representation for the 2SQR(θ, q) estimator with a possible bias term \( B_0 \) as follows:\(^7\).

Proposition 1. Suppose that Assumptions 1-3 hold. Then, the asymptotic representation for the 2SQR(θ, q) estimator is:

\[
T^{1/2}(\hat{\alpha} - \alpha_0 - B_0) = RT^{-1/2} \sum_{t=1}^{T} x_t q \psi_\theta(v_t)
+ (1 - q) R Q_0 T^{1/2}(\hat{\pi} - \pi_0 - B_\pi)
- R Q_0 T^{1/2}(\Pi - \Pi_0 - B_\Pi) \gamma_0 + o_p(1),
\]

where \( B_0 = R Q_0 \{(1 - q) B_\pi - B_\Pi \gamma_0 \}, R = Q_{zz}^{-1} H(\Pi_0)' Q_{xz}^* = H(\Pi_0)' Q_0 H(\Pi_0) \) and \( \Pi_0 = \Pi_0 + B_\Pi. \)

The asymptotic representation of 2SQR(θ, q) is composed of four additive right-hand-side terms. The first term does not perturb consistency under Assumption 3(iv) and corresponds to the contribution of the second stage to the uncertainty of the estimator. The second and third terms correspond to the respective contributions of \( \hat{\pi} \) and \( \Pi \) to this uncertainty. Then, when \( \hat{\pi} \) and \( \Pi \) are consistent, it is straightforward to show that the 2SQR(θ, q) is consistent. If \( q = 1 \), the influence of \( \hat{\pi} \) vanishes. The presence of the contribution of \( \hat{\pi} \) may imply contradictions between some chosen restrictions on errors in the first and second stages and cause biases, which will be explained in detail in the next section. The formula of \( B_0 \) is obtained as the value allowing \( T^{1/2}(\hat{\alpha} - \alpha_0 - B_0) = O_p(1), \)

\(^7\)Other derivations of asymptotic representation of quantile regression estimators have been developed (Phillips, 1991, Pollard, 1991), which involve slightly different assumptions. Other possible approach to the asymptotic representation of 2SQR is in Chen et al. (2003).
and is derived from the first-order conditions of the second-stage estimation, which is discussed in
detail in Appendix A. We note that the consistency of $\hat{\alpha}$ to $\alpha_0 + B_\alpha$ naturally follows from Proposition 1.

4 The Asymptotic Bias

In this section, we discuss the relationship linking the bias terms in the first stage estimators
$(B_\pi, B_{\Pi})$ and the second stage estimators $(B_\alpha)$. We first state the following proposition.

Proposition 2. Suppose that both $B_\pi$ and $B_{\Pi}$ have non-zero components only for their first
$K_1$ elements; i.e., $B_\pi = \begin{bmatrix} B_{\pi,1} \\ B_{\pi,2} \end{bmatrix}$ and $B_{\Pi} = \begin{bmatrix} B_{\Pi,1} \\ B_{\Pi,2} \end{bmatrix}$ with $B_{\pi,1}$ and $B_{\Pi,1}$ being the first $K_1$
components, and $B_{\pi,2} = 0$ and $B_{\Pi,2} = 0$. Under this restriction, we have:

$$B_\alpha = \begin{bmatrix} (1 - q)B_{\pi,1} - B_{\Pi,1}\gamma_0 \\ 0_G \end{bmatrix},$$

where $0_G$ is a $G$ vector of zeros.

The sufficient stochastic assumptions for this characterization of the bias transmission are very
general, including general serial correlations and heteroskedasticity.

When the first-stage estimation is performed on the two reduced form equations in (2) and (3),
the explanatory or instrumental variables $x_t$ consists of vectors $x_{1t}$ and $x_{2t}$. If a non-zero asymptotic
bias is present only in the coefficients of $x_{1t}$ in the first-stage estimators ($\hat{\pi}$ and $\Pi$), which is the case
on which we focus, then the non-zero asymptotic bias in the second-stage estimator ($\hat{\alpha} = [\hat{\beta}', \gamma']$)
is exclusively confined to the coefficients of $x_{1t}$; that is, only $\hat{\beta}$ is asymptotically biased. Therefore,
the parameter ($\gamma_0$) for the endogenous variable $Y_t$ in the structural equation in (1), in which applied
economists are usually interested, can be consistently estimated.

This is useful because empirical researchers may often pay little attention to the intercept term,
whereas the estimates of the slope coefficients often carry more explanatory meaning. One example
of such situation is when one performs the first-stage estimation of (2) and (3) by LS. Indeed,
under Assumption 3(iv) or under the stronger quantile-independence condition corresponding to
constant quantile treatment effect models, the zero mean condition on $v_t$ is not satisfied. Then, the
intercept LS estimator cannot be consistent (unless the probability support of $v_t$ does not include
the interval between the mean and the quantile of interest), while the remaining slope coefficients
still can be consistently estimated. Moreover, depending on distributional restrictions on $V_t$ that
the researcher is willing to impose, she may choose an estimator for $\Pi_0$ such that its intercept term
only is inconsistent.

We emphasize that the researcher, if she or he wishes, can eliminate the bias completely by
choosing $q = 1$ (i.e., not using the composite dependent variable) and by placing some suitable
restriction on $V_t$ to make $\Pi$ consistent. In this paper, we propose instead choosing $q \neq 1$ and
selecting first-stage estimators with bias terms confined only to their intercept parts in order to
allow for efficiency gains for the second stage slope estimators. In that case, the slope coefficients in
the structural equation can be consistently estimated while its asymptotic variance will depend on
$q$. This generates a trade-off between the bias in the intercept estimator (i.e., the first element of
$\hat{\alpha}$) and the efficiency of the slope estimator (i.e., all of the remaining elements of $\hat{\alpha}$). Our approach
contrasts with the statistics literature on shrinking estimators where all of coefficients estimators
are biased to improve their efficiency.
Let \( v^*_t = v_t - F^{-1}_{v_t|x_t}(\theta) \). Consider \( E(\psi_\theta(v^*_t)|x_t) = \theta - P[v^*_t \leq 0|x_t] = \theta - P\left[v_t \leq F_{v_t|x_t}^{-1}(\theta)|x_t\right] = \theta - \theta = 0 \), which is the conditional quantile restriction characterising \( v^*_t \). As a consequence, we obtain the reduced-form quantile regression restriction, provided we accept the introduction in the regression of a possible nuisance bias term \( F_{v_t|x_t}^{-1}(\theta) \) that may affect all coefficients of the model when it is linear in \( x_t \), or even be nonlinear in \( x_t \). Let us now assume that \( u_t \) and \( V_t \) are independent of \( x_t \), defined as \( x_t \) except constant variables. Since \( v_t = u_t + V_t\gamma_0 \), this assumption implies \( F_{v_t|x_t}^{-1}(\theta) = F_{u_t}^{-1}(\theta) \) and the nuisance term is confined to the intercept. Then, according to Proposition 2, a bias is generated exclusively on the intercept term of the structural model.

However, this condition of independence for all \( \theta \) also implies constant effects in the quantile regressions of interest. Although the above characterisation of instrumental variables may be deemed to be strong by some authors, it is usually the way instrumental variables are intuitively found by empiricists: variables that are not connected at all with the model errors seen as a remainder of somehow from equivalent restrictions, with perhaps the exception of the intercept. In particular, under the independence/constant effect hypothesis, the estimates based on the conditional quantile of the reduced form can be used to recover the slope estimator of the conditional quantile of the structural form.

5 Asymptotic Normality and Covariances with LS and Trimmed-LS Predictions

In this section, we examine the use of (non-robust) LS estimation and (robust) trimmed-least-squares (TLS) estimation of \( \pi_0 \) and \( \Pi_0 \) in the first stage in this section. There are several reasons to consider LS estimation in the first stage. First, LS estimation is popular and can be readily used. Second, using LS estimation in the first stage may improve the efficiency of the final two-stage quantile estimator, which may explain why empirical researchers have been using this technique.\(^8\) Alternatively, using TLS in the first stage guarantees the robustness of this estimation stage, while some efficiency may be lost. Using twice the same quantile regression in both stages has been examined in Kim and Muller (2004). In that case, there is no consistency issue, but also no opportunity for asymptotic variance reduction either as the asymptotics is invariant to the choice of parameter \( q \).

Since we consider constant quantile treatment effect models, it is not restrictive to assume that \( x_t \) is mean-independent of \( v_t \) and \( V_t \) as in Assumption 3’ below. The following assumption is more restrictive than what is necessary for Assumption 2 or for Proposition 2, given that we now wish to confine the possible bias to the intercept exclusively.

**Assumption 3’.** (i) \( E(v_t|x_t) = E(v_t) \) and (ii) \( E(V_t|x_t) = E(V_t) \).

Assumption 3’ imposes the orthogonality of the reduced form errors with all non-constant

\(^8\)Examples include Arias et al. (2001), Garcia et al. (2001), Chevapatrakul et al. (2009) and Chortareas et al. (2012).
exogenous variables. As stated before, an issue of using LS estimation in the first-stage is that the condition \( E(v_t) = 0 \), which makes the LS estimator \( \hat{\pi} \) in (3) consistent, conflicts with the restriction \( E(\psi_g(v_t)) = 0 \), which is implied by Assumption 3(iv); that is, the \( g^{th} \) quantile and the mean of \( v_t \) cannot be zero at the same time. Then, to be able to use the usual Bahadur representation of the LS estimator, we define the centered errors \( v_t^* = v_t - E(v_t) \) and \( V_t^* = V_t - E(V_t) \). By construction, \( E(v_t^*|x_t) = 0 \) and \( E(V_t^*|x_t) = 0 \).

Under Assumption 3', the reduced form equations for \( Y_t \) and \( y_t \) in (2) and (3) can be rewritten by reallocating the bias to the intercept coefficient as follows:

\[
Y_t' = x_t'\Pi_0^* + V_t'^*,
\]

where \( \Pi_0 = \Pi_0 + B_{\Pi} \) with \( B_{\Pi} = [E(V_t)',0',\ldots,0]' \), which is a \((K \times G)\) matrix, and

\[
y_t = x_t'\pi_0^* + v_t^*,
\]

where \( \pi_0^* = \pi_0 + B_{\pi} \) with \( B_{\pi} = [E(v_t),0,\ldots,0]' \), which is a \((K \times 1)\) matrix.

The bias \( B_{\pi} \) is generally non-zero for \( q \neq 1 \). In contrast, \( B_{\Pi} \) can be non-zero or not, even with \( q = 1 \), depending on the restrictions imposed on \( V_t \). In the case \( q = 1 \), a natural specification suggests \( E(V_t|x_t) = 0 \) when using OLS to estimate (2) and no bias at all. In other cases, \( B_{\pi} \) and \( B_{\Pi} \) may have to be taken into account.

Let \( \Pi \) and \( \pi \) be the first-stage LS estimators based on (6) and (7) respectively and let \( \hat{\alpha} \) be the corresponding 2SQR(\( \theta, q \)) estimator. The asymptotic representations of \( \Pi \) and \( \pi \) are obtained and plugged into the formula in Proposition 1 to obtain the asymptotic representation for \( \hat{\alpha} \) as follows:

\[
T^{1/2}(\hat{\alpha} - \alpha_0 - B_\alpha) = RT^{-1/2}\sum_{t=1}^{T} x_t q \psi_g(v_t) - RQ_0Q^{-1}T^{-1/2}\sum_{t=1}^{T} x_t (q v_t^* - u_t^*) + o_p(1).
\]

Due to the characterization of \( B_\alpha \) in Proposition 2, we have \( B_\alpha = ((1-q)E(v_t) - E(V_t)\gamma_0,0,\ldots,0)' \). The intercept estimator is inconsistent, while the slope estimators are not. To derive the asymptotic normality of \( \hat{\alpha} \), we impose the following additional regularity assumptions.

**Assumption 4.** (i) There exist finite constants \( \Delta_\alpha \) and \( \Delta_{V_j} \) such that \( E|x_{ti}v_t^*|^3 < \Delta_\alpha \) and \( E|x_{ti}V_{jt}^*|^3 < \Delta_{V_j} \), for all \( i, j \) and \( t \).

(ii) The covariance matrix \( V_T = var \left( T^{-1/2} \sum_{t=1}^{T} S_t \right) \) is positive definite for \( T \) sufficiently large, where \( S_t = (q \psi_g(v_t), q v_t^* - u_t^*)' \otimes x_t, u_t^* = v_t^* - V_t'^*\gamma_0 \) and \( \otimes \) is the Kronecker product.

Assumption 4(ii) is used to apply a CLT appropriate for the \( \alpha \)-mixing case. It can be much relaxed in the iid case. Assumption 4(ii) ensures the positive definiteness of the variance in the CLT.

**Proposition 3.** Suppose that Assumptions 1, 3, 3' and 4 hold. Then,

\[
D_T^{-1/2}T^{1/2}(\hat{\alpha} - \alpha_0 - B_\alpha) \overset{d}{\to} N(0, I),
\]

where \( D_T = MV_TM' \) and \( M = R[I, -Q_0Q^{-1}] \).
The asymptotic result in Proposition 3 shows that the asymptotic variance-covariance of the 2SQR(θ, q) estimator depends on the combination weight q through V_T, while the consistency of the slope estimator is not affected by the presence of q. To improve efficiency, q can be replaced with an optimal value (q*) obtained by minimising the asymptotic covariance matrix shown in Proposition 3. However, there are many ways of minimising a multi-dimensional covariance matrix. For example, one may minimise some norm of the matrix (e.g., the mean square error). One may also minimise the standard error for a given coefficient of interest in the structural model.

For all these procedures and in some special cases (e.g., IID), the effect of q on D_T is concentrated in a scalar function that gathers the contribution of all the error terms to this matrix. Then, a unique and explicit solution q* can be obtained. In the general case, q* can also be made explicit when the MSE is minimised. Consistent preliminary estimators of q* do not perturb the asymptotic properties of the 2SQR, which can be characterised as a MINPIN estimator (Andrews, 1994, p. 2263), as long as a stochastic equicontinuity condition of the global empirical process is valid.

We now exhibit a case with an explicit formula for q*. Assume \{ (x_t', u_t, v_t) \} is iid and \( f_t(0|x_t) = f(0) \), for any t. Then, the asymptotic covariance matrix in Proposition 3 simplifies into \( \sigma_0^2(q)Q_z^{-1} \), where \( \sigma_0^2(q) = E(\epsilon_t^2), \zeta_t = qf(0)^{-1}\psi\theta(v_t) + u_t^* - qv_t^* \) and \( Q_z = H(\Pi_0)^tQH(\Pi_0) \). In this case, we can easily obtain the optimal weight as in the following lemma.

**Lemma 2.** Suppose that Assumptions 1.3, 3' and 4 hold. In addition, we assume that \{ (x_t', u_t, v_t) \} is iid and \( f_t(0|x_t) = f(0) \), for any t. Then, the optimal weight minimizing the asymptotic variance of \( \hat{\alpha} \) is given by:

\[
q^* = \frac{E(u_t^*u_t^*) - f(0)^{-1}E(\psi\theta(v_t)u_t^*)}{f(0)^{-2}\theta(1-\theta) + E(v_t^*)^2 - 2f(0)^{-1}E(\psi\theta(v_t)v_t^*)}.
\]

A consistent estimator for \( q^* \) is obtained by substituting a consistent kernel-estimator \( \hat{f}(0) \) for \( f(0) \), and residuals for error terms:

\[
\hat{q} = \frac{\sum_{t=1}^T \hat{v}_t^* \hat{u}_t^* - \hat{f}(0)^{-1}\sum_{t=1}^T \psi\theta(\hat{v}_t)\hat{u}_t^*}{T \hat{f}(0)^{-2}\theta(1-\theta) + \sum_{t=1}^T \hat{v}_t^*^2 - 2\hat{f}(0)^{-1}\sum_{t=1}^T \psi\theta(\hat{v}_t)\hat{v}_t^*},
\]

where \( \hat{u}_t^* = \hat{v}_t^* - \hat{V}_t^*\hat{\gamma}, \hat{v}_t^* = y_t - x_t^*\hat{\pi}, \hat{V}_t^* = Y_t - x_t^*\hat{\Pi}, \hat{\gamma} = y_t - x_t^*\hat{\pi}_\theta \) and \( \hat{\pi}_\theta = \arg\min_{\pi} \sum_{t=1}^T \rho(y_t - x_t^*\pi) \). The omitted proof for the consistency of \( \hat{q} \) is straightforward.

To address robustness concerns, we now propose an estimator based on a robust first-stage estimator: the symmetrically trimmed-LS estimator (TLS). The TLS of \( \pi \) in the model \( y = X\pi + v \) is \( \hat{\pi}_{TLS} = (X'AX)^{-1}XAy \), where \( A = (a_{ij}), i, j = 1, ..., p \) and \( a_{ij} = I_{[i=j \text{ and } X_i'\hat{\pi} < y < X_i'\hat{\pi}(1-\mu)]} \). \( \hat{\pi}(\mu) \) is the quantile regression estimator centered on a given quantile \( \mu \) to be chosen a priori. Chen and Portnoy (1996) provide the TLS Bahadur representation. Let \( \hat{\alpha} \) be the estimator built from the TLS in the first stage and the quantile regression in the second stage. We adjust Assumptions 3' and 4 as follows, with analogous interpretations of the different conditions.

**Assumption 3'' (i)** \( E(v_t|x_t) - E(t_-v_t) - \mu \left[ F_{v^{-1}}(\mu) + F_{v^{-1}}(1-\mu) \right] = 0, \)
where \( t_-v_t \equiv v_t.I_{[F_{v^{-1}}(\mu) < v_t < F_{v^{-1}}(1-\mu)]} \) is the truncated error term.

(ii) \( E(V_{it}|x_t) - E(t_-V_{it}) - \mu \left[ F_{v^{-1}}(\mu) + F_{v^{-1}}(1-\mu) \right] = 0, \) where \( V_{it} \) is the \( i^{th} \) element of \( V_t \) and \( t_-V_{it} = V_{it}.I_{[F_{v^{-1}}(\mu) < v_t < F_{v^{-1}}(1-\mu)]} \) is the truncated error term.

**Assumption 4' (i)** There exist finite constants \( \Delta_\pi \) and \( \Delta_{\hat{\gamma}_i} \) such that \( E|\hat{v}_t^*|^3 < \Delta_\pi \) and
\[ E[x_t \tilde{V}_{jt}]^3 < \Delta_{V_j} \text{ for all } i, j \text{ and } t, \]

where

\[ \tilde{v}_t^* = v_t - E(t \_v_t) - \mu \left[ F_{v}^{-1}(\mu) + F_{v}^{-1}(1 - \mu) \right] \]

and \( \tilde{V}_{jt} = V_{jt} - E(t \_V_{jt}) - \mu \left[ F_{V_j}^{-1}(\mu) + F_{V_j}^{-1}(1 - \mu) \right] \).

(ii) The covariance matrix \( \tilde{V}_T = \text{var} \left( T^{-1/2} \sum_{t=1}^{T} \tilde{S}_t \right) \) is positive definite for \( T \) sufficiently large, where \( \tilde{S}_t = (q \psi_{\theta}(v_t), q \tilde{v}_t^* - \tilde{u}_t^*)' \otimes x_t \).

The Bahadur representation, obtained from Proposition 1, and the representation for TLS (Ruppert and Carroll, 1980) can be used to obtain the following asymptotic representation of \( \tilde{\alpha} \):

\[ T^{1/2}(\tilde{\alpha} - \alpha_0 - \tilde{B}_\alpha) = RT^{-1/2} \sum_{t=1}^{T} x_t q \psi_{\theta}(v_t) \]

\[ -RQ_0Q^{-1}T^{1/2} \sum_{t=1}^{T} x_t (q \tilde{v}_t^* - \tilde{u}_t^*) + o_p(1), \]

where the bias vector \( \tilde{B}_\alpha \) is such that the first element only is non-zero. The non-zero bias term is given by \( (1 - q)\{E(t \_v_t) + \mu \left[ F_{v}^{-1}(\mu) + F_{v}^{-1}(1 - \mu) \right] \} - B_{\Pi,1} \gamma_q \), where \( B_{\Pi,1} \) is a \( G \)-row vector whose \( j \)th element is given by \( E(t \_V_{jt}) + \mu \left[ F_{V_j}^{-1}(\mu) + F_{V_j}^{-1}(1 - \mu) \right] \). The asymptotic representation (10) together with Assumptions 3" and 4' delivers the following asymptotic normality of \( \tilde{\alpha} \).

**Proposition 4.** Suppose that Assumptions 1, 3, 3" and 4' hold. Then,

\[ \tilde{D}_T^{-1/2}T^{1/2}(\tilde{\alpha} - \alpha_0 - \tilde{B}_\alpha) \overset{d}{\rightarrow} N(0, I), \]

where \( \tilde{D}_T = MV_T M' \) and \( M = R[I, -Q_0Q^{-1}] \).

As before, if \( \{ (x_t', u_t, v_t) \} \) is iid and \( f_t(0|x_t) = f(0) \) for any \( t \), then the asymptotic matrix of \( \tilde{\alpha} \) is \( \tilde{\sigma}_0^2(q)Q_{zz}^{-1} \), where \( \tilde{\sigma}_0^2(q) = E(\tilde{c}_t^2), \tilde{c}_t = q f(0)^{-1} \psi_{\theta}(v_t) + \tilde{u}_t^* - q \tilde{v}_t^* \) and \( Q_{zz} = H(\Pi_0)'Q_0H(\Pi_0) \), and \( \Pi_0 = \Pi_0 + \tilde{B}_\Pi \). In this case, it can be proved that the optimal value of \( q \) minimizing \( \tilde{\sigma}_0^2(q) \) is given by:

\[ q^* = \frac{E(\tilde{c}_t^2)}{E(\tilde{c}_t^2)^{-2} - 2 f(0)^{-1} E(\tilde{c}_t^2)^{-1} E(\psi_{\theta}(v_t)\tilde{c}_t^*)}. \]

A consistent estimator for \( q^* \) is similarly obtained as follows:

\[ \hat{q} = \frac{\sum_{t=1}^{T} \tilde{c}_t^2 \tilde{u}_t^* - \hat{f}(0)^{-1} \sum_{t=1}^{T} \psi_{\theta}(v_t)\tilde{u}_t^*}{T \hat{f}(0)^{-2} \theta(1 - \theta) + \sum_{t=1}^{T} \tilde{c}_t^2 - 2 \hat{f}(0)^{-1} \sum_{t=1}^{T} \psi_{\theta}(v_t)\tilde{c}_t^*}, \]

where \( \tilde{u}_t^* = \tilde{v}_t^* - \tilde{V}_t' \tilde{\pi}, \tilde{v}_t^* = y_t - x_t' \tilde{\pi}_{TLS}, \tilde{V}_t' = Y_t' - x_t' \tilde{\Pi}_{TLS}, \tilde{\pi} = y_t - x_t' \tilde{\pi}_{TLS} \) and \( \tilde{\pi}_{TLS} \) is the \( \tilde{\pi} \).

In the next section, we present Monte Carlo simulation results, notably showing how much variance reduction can be achieved in finite samples with our method.\(^9\)

---

\(^9\)The case where the first stage is a quantile regression with the same quantile as in the second stage is reported in Kim and Muller (2004), with directly comparable tables.
6 Monte Carlo Simulations

6.1 Simulation Set-up

The data generating process used in the simulations is described in Appendix B. We study the finite sample properties of our two proposed two-stage estimators: (1) the OLS plus quantile regression estimator (2SQR1), and (2) the TLS plus quantile regression estimator (2SQR2). We impose $E(\psi_\theta(v_t)|x_t) = 0$ for each given $\theta$. That is: for each $\theta$, we regenerate the error terms such that $E(\psi_\theta(v_t)|x_t) = 0$ is satisfied, which means that we consider models centered differently according to the different $\theta$. As explained in Appendix B, the equation of interest is assumed to be over-identified and the parameter values are set to $\beta' = (\beta_{0.1}, \beta_{0.2}) = (1, 0.2)$ and $\gamma = 0.5$. We generate the error terms by using three alternative distributions: the standard normal $N(0,1)$, the Student-$t$ with 3 degrees of freedom $t(3)$ and the Lognormal $LN(0,1)$. The exogenous variables $x_t$ are drawn independently from the errors from a normal distribution. For each of the 1000 replications, we estimate the parameter values $\beta$ and $\gamma$ using 2SQR1 and 2SQR2, and we calculate the deviations of the estimates from the true values. Then, we display the sample mean and sample standard deviation of these deviations over the 1,000 replications. The optimal value $q^*$ is obtained by simulating the formula in (8) or (11), while $\hat{q}$ is estimated through (9) or (12).

6.2 Results

We first discuss the results for the 2SQR1($\theta, q$) with $N(0,1)$, $t(3)$ and $LN(0,1)$ errors, shown in Tables 1-3 for the case of iid errors. We first discuss the results when the error terms are drawn from $N(0,1)$ shown in Table 1. In all cases, as expected, the intercept estimate exhibits biases that do not vanish as the sample size increases. On the other hand, the 2SQR1($\theta, q$) estimates for the slope parameters ($\beta_1$ and $\gamma$) are unbiased for all specifications, all evaluations of $q$ and all $\theta$s and even with a sample size as small as 50. Using the optimal value $q^*$ dramatically improves the accuracy of the 2SQR1($\theta, q$) as compared to the case $q = 1$. The optimal values $q^*$ are close to zero, which can be viewed as related to a kind of inverse least-squares extraction of the structural parameters from the reduced-form parameters. This is what pushing $\hat{q}$ to zero does, as can be seen in (5). The gain is larger for the extreme quantiles ($\theta = 0.05$ and 0.95) than for the middle quantiles ($\theta = 0.25, 0.5$ and 0.75). Even with $T = 50$, using $\hat{q}$ can substantially improve efficiency as compared to $q = 1$. The estimation accuracy of $\hat{q}$ and the efficiency gain improve as the sample size increases. With $T = 300$, using $\hat{q}$ or $q^*$ is almost indifferent for estimating $\alpha_0$, although the estimated values of $\hat{q}$ are not always very close to $q^*$.

Table 2 shows the results for the Student-t distribution case. As expected, with fat tails $t(3)$ errors the standard deviations of the sampling distributions of the 2SQR1($\theta, q$) are much larger than with normal errors. As before, the variance reductions from using $q^*$ are small for middle quantiles, while substantial reductions can be achieved for extreme quantiles. The standard deviations are the largest for the lognormal case, where using $q^*$ always yields outstanding efficiency gains. For right-skewed distributions, quantile regressions are typically inaccurate for large quantiles. In this case, our method generates large efficiency gains. For example, considering the case with $T = 300$, the standard error for $\hat{q}$ with $q = 1$ is 0.91, while it is reduced to 0.25 with $q = \hat{q}$. However, there is virtually no efficiency gain with small values of $\theta$ less than around 0.5.

Given the generally substantial efficiency gains, it is natural to ask how close the reduced variance is to the Cramer-Rao lower bound. We have calculated the CR bound numerically for

---

10 We have conducted the same set of simulations for the case of heteroscedastic errors and have found that the results are qualitatively the same as in the iid case.
each distribution in Table 4(a) for $T = 50$ and Table 5(a) $T = 300$. Table 4(a) shows the simulated asymptotic standard deviations for 2SLS and $2SQR1(\theta, \hat{q})$ with $\theta = 0.25, 0.50, 0.95$, along with the simulated CR bounds with $T = 50$. We only discuss the slope coefficients as the intercept coefficient estimate is biased.

For a small sample size such as $T = 50$, the 2SLS efficiency loss is not negligible even for the normal distribution case and the efficiency loss becomes surprisingly large for both $t(3)$ and LN$(0,1)$. On the other hand, $2SQR1(\theta, \hat{q})$ attains the CR bounds at the middle quantiles such as $\theta = 0.25, 0.5$ and 0.75 for the normal distribution case. Moving to the Student-t distribution case, $2SQR1(\theta, \hat{q})$ is much more efficient than the 2SLS again at the middle quantiles ($\theta = 0.25, 0.5$ and 0.75). For example, we observe approximately 24% efficiency gain at $\theta = 0.5$. Finally, under lognormality, 2SLS performs badly relative to the CR bounds, while $2SQR1(\theta, \hat{q})$ stays closer to the CR bounds for small and middle quantiles than 2SLS.

When we increase the sample size to $T = 300$, we have qualitatively the same results as shown in Table 5(a). For the normal errors, both 2SLS and $2SQR1(\theta, \hat{q})$ attain the CR bounds. However, all the previous observations still hold for the other two error distributions $t(3)$ and LN$(0,1)$; i.e., (i) $2SQR1(\theta, \hat{q})$ is more efficient than 2SLS at the middle quantiles for $t(3)$, and (ii) $2SQR1(\theta, \hat{q})$ is more efficient than 2SLS at the low and middle quantiles for LN$(0,1)$.

Let us now turn to $2SQR2$ based on the TLS at the first stage.\footnote{We have also tried LAD in the first-stage, as in Chen and Portnoy (1996). However, the results are almost identical to that of the $2SQR2$ so that we do not include the results in the paper, while they are available upon request. What seems to matter here is the robustness of the first stage estimator.} According to our simulations, using the trimming value of $\mu = 0.25$ yields more accurate results than other trimming values such as 0.05 or 0.10.\footnote{One exception is the normal distribution case with $T = 50$, in which case trimming at 0.25 is only slightly inferior than 0.1.} For a large sample size such as $T = 300$, trimming at 0.05, 0.10 or 0.25 is almost indifferent. Hence, we focus on the case $\mu = 0.25$. The results for $2SQR2$ are reported in Tables 4(b) and 5(b), respectively for $T = 50$ and $T = 300$ where the two cases ($q = 1$ and $q = \hat{q}$) are shown and compared. As clearly demonstrated in the two tables, our proposed variance reduction method works again very well with the $2SQR2$ estimator.

The $2SQR2(\theta, \hat{q})$ appears to perform uniformly better than the $2SQR2(\theta, q = 1)$, except for $T = 50$ at the median for $t(3)$ and at a few low quantiles for LN$(0,1)$ – probably because of sampling errors since this irregularity vanishes when $T = 300$. The improvement from moving from $q = 1$ to $q = \hat{q}$ is sizeable at quantile 0.95 for symmetric errors (up to 60% reduction in standard deviation) and at large quantiles for asymmetric errors (up to 80% reduction). The $2SQR2(\theta, \hat{q})$ clearly improves on the $2SQR1(\theta, \hat{q})$ for both $t(3)$ and LN$(0,1)$, while the reverse is true for normal errors.

Let us finally compare the most interesting two estimators; i.e. $2SQR1(\theta, \hat{q})$ and $2SQR2(\theta, \hat{q})$ in Tables 4 and 5. Under normal errors, the $2SQR1(\theta, \hat{q})$ and the $2SQR2(\theta, \hat{q})$ both almost reach the CR bound, whatever the considered quantile. Here, reformulating the dependent variable is fruitful, especially for upper quantiles for which it allows massive efficiency gains. The $2SQR2(\theta, q = 1)$ is slightly outperformed by the $2SQR1(\theta, \hat{q})$, perhaps because trimming here only discards information. With Student errors, the $2SQR2(\theta, \hat{q})$ is often the more accurate estimator, yielding results fairly close to the CR bound. Under lognormality, none of the studied estimators approaches the CR bound. However, using the $2SQR2(\theta, \hat{q})$ generally yields the best accuracy. For upper quantiles, reformulating the dependent variables delivers huge efficiency gains.

It is interesting to reflect on the proximity of the results of the $2SQR1(\theta, \hat{q})$ and the $2SQR2(\theta, 1)$ in the light of the non-robustness of the OLS and the robustness of the TLS. Redefining the dependent variable may improve the robustness of the two-stage estimator through the reduction
of the influence of outliers for the errors $v_t$, even when the first-stage estimator is non-robust. This effect, apparent in the formula of the asymptotic representation, is confirmed in the small sample simulations. Thus, specific estimators of $q$ could also be chosen to enhance robustness.

7 Conclusion

In this paper, we develop a new method of variance reduction for two-stage estimation procedures and apply it to the case of two-stage quantile regression allowing for random regressors as well as non-iid error terms. In this setting, we show that an asymptotic bias that would occur in the first-stage reduced-form estimates of the coefficients of the exogenous variables in the structural equation is integrally and exclusively transmitted to the coefficients of the same variables in the second-stage. At this occasion, we show that the structural approach and the fitted-value approach to two-stage quantile regressions amount to estimating the same structural slope coefficients, under a natural instrumental variable assumption corresponding to the constant effects case of quantile regressions.

Following an original idea in Amemiya (1982), we reformulate the dependent variable as a weighted mean of the original dependent variable and its fitted value. Such a combination introduces a trade-off between an asymptotic bias on the intercept of the equation of interest on the one hand, and the variance reduction of the slope estimator on the other hand. Using such a trade-off, we can improve the efficiency of the slope estimator at the expense of making the intercept estimator inconsistent.

We derive the asymptotic normality and the asymptotic variance-covariance matrix of such two-stage quantile regression estimators. Then, we apply our variance reduction method to these specific two-stage quantile regression estimators. Our Monte Carlo simulation results show massive efficiency gains in many cases. In particular, our new method alleviates the well-known poor efficiency of quantile regressions at extreme quantiles. Two important arguments to use quantile regression jointly with variance-reduction are first that it yields more accurate or equivalent estimates than OLS, and second that it does not require the knowledge of the distribution shape, which is a drawback of maximum likelihood estimators.

Let us emphasize two practical principles in our approach. First, the first-stage estimators should be carefully selected so as to preserve efficiency, robustness or other desired properties. Our simulation results suggest that OLS should perform well under normality, while trimmed least-square should be more accurate and more robust for heavy tails or asymmetric error distributions. Second, one should reformulate the dependent variable as proposed, in such a way that a selected variance criterion is minimized. The choice of the variance criterion may be left to the researcher, while minimising the MSE seems to be a natural choice.

We finally recap the computation steps for trimmed least-squares plus quantile regression: (1) trimmed least-squares for the reduced-form equation and the ancillary equations, (2) computation of the fitted-values for the endogenous regressors of the structural equation, (3) preliminary quantile regression of the structural equation where the endogenous regressors are substituted with their fitted values, (4) estimation of the density of the reduced form error at the quantile of interest, (5) estimation of the optimal weight for the reformulation, using residuals and density estimates from the previous stages, (6) reformulation of the dependent variable using the optimal weight, (7) final quantile regression of the structural equation.

It is worth mentioning as a word of conclusion that the proposed method for variance reduction is not necessarily limited to two-stage quantile regression. In fact, our approach might be generalized to any two-stage regression where the use of a composite dependent variable does not disturb the
consistency property of the final estimator.
References

Appendix A: Mathematical Proofs

Proof of Lemma 1: Let \( M_{T_1}^*(\zeta) = T^{-1/2} \sum_{t=1}^{T} m^*_t(w_t, \zeta) \), where \( \zeta \) is a \( K \times 1 \) vector, \( w_t = (v_t, x'_t)' \), \( m^*_t(w_t, \zeta) = x_t \psi_v(qv_t - x'_t \zeta) \) and \( x_t \) is the \( i^{th} \) element in \( x_t \). We define \( V_{T_1}^*(\zeta) = M_{T_1}^*(\zeta) - E(M_{T_1}^*(\zeta)) \). We shall show that \( \{ V_{T_1}^*(\zeta) : T \geq 1 \} \) is stochastically equicontinuous. To do so, we use Theorem II.8 in Andrews (1990) for which the following two conditions must be verified: (a) \( m^*_t(w_t, \zeta) \) is a type IV class function with index \( p \geq 2 \); that is, for all bounded \( \zeta \) in \( R^K \) and for all \( L_1 > 0 \) in a neighborhood of zero,

\[
\sup_{t \leq T, T > 1} \left[ E \left( \sup_{\zeta:||\zeta||L_1 < L_1} |m^*_t(w_t, \zeta_1) - m^*_t(w_t, \zeta)|^p \right) \right]^{1/p} \leq CL_1^\psi \tag{13}
\]

for some positive constants \( C \) and \( \psi \) and (b) \( \{ w_t \} \) is \( \alpha \)-mixing of size \( -\frac{(2K+\psi)(K+2\psi)}{\psi^2} \).

We first verify (a) for \( p = 2 \). Consider a constant \( L_1 \) close to zero and a finite value of \( \zeta \) in \( R^K \). Note that

\[
|m^*_t(w_t, \zeta_1) - m^*_t(w_t, \zeta)| = |x_t||1_{qv_t - x'_t \zeta \leq 0} - 1_{qv_t - x'_t \zeta \geq 0}|
\]

\[
= |x_t||1_{A \leq 0} - 1_{B \geq 0}| \leq |x_t||1_{||A|| \leq |A-B|}| \leq |x_t||1_{||qv_t - x'_t \zeta|| \leq ||x_t|| \times ||\zeta_1 - \zeta||}|,
\]

where \( A = qv_t - x'_t \zeta \) and \( B = qv_t - x'_t \zeta_1 \). Hence, we have

\[
\sup_{\zeta_1:||\zeta_1 - \zeta|| < L_1} |m^*_t(w_t, \zeta_1) - m^*_t(w_t, \zeta)|^2 \leq x_t^2 \sup_{\zeta_1:||\zeta_1 - \zeta|| < L_1} 1_{||qv_t - x'_t \zeta|| \leq ||x_t|| \times ||\zeta_1 - \zeta||} \leq x_t^2 1_{||qv_t - x'_t \zeta|| \leq ||x_t||L_1},
\]

which implies

\[
E \left( \sup_{\zeta_1:||\zeta_1 - \zeta|| < L_1} |m^*_t(w_t, \zeta_1) - m^*_t(w_t, \zeta)|^2 \right)
\]

\[
\leq E \left( x_t^2 P_{x_t} [||qv_t - x'_t \zeta|| \leq ||x_t||L_1] \right) = E \left( x_t^2 \int_{L_0}^{U_0} f_{v|\zeta}(\lambda|x_t)|d\lambda \right) \quad (\because q > 0)
\]

\[
\leq E \left( x_t^2 \int_{L_0}^{U_0} f_{0|\zeta}(\lambda|x_t)|d\lambda \right) \quad (\because \text{Assumption 3(ii)})
\]

\[
= \frac{2f_0}{q} E \left( x_t^2 ||x_t|| \right) L_1,
\]

where \( P_{x_t} \) is the conditional probability function given \( x_t \), \( U_0 = q(1)(x'_t \zeta + ||x_t||L_1) \) and \( L_0 = q^{-1}(x'_t \zeta - ||x_t||L_1) \). Hence,

\[
\sup_{t \leq T, T > 1} \left[ E \left( \sup_{\zeta_1:||\zeta_1 - \zeta|| < L_1} |m^*_t(w_t, \zeta_1) - m^*_t(w_t, \zeta)|^2 \right) \right]^{1/2} \leq CL_1^{1/2}
\]

for some constant \( C \) because of Assumption 3(v). Hence, condition (a) is satisfied with \( \psi = 1/2 \).

Next, we turn to condition (b). Since \( \psi = 1/2 \),

\[
- \frac{(2K+\psi)(K+2\psi)}{\psi^2} = - \frac{(2K + \frac{1}{2})(K+1)}{\frac{1}{4}} = -2(4K + 1)(K + 1).
\]
Next, we show that $T^2 V_T(\zeta_1) = 2 T^2 V_T(\zeta_2)$. Hence, condition (b) is a consequence of Assumption 1. Therefore, by Theorem II.8 in Andrews (1990), $\{V^2_T(\zeta) : T \geq 1\}$ is stochastically equicontinuous, which implies that $V^2_T(\zeta)$ is also stochastically equicontinuous. Then, for any constant sequence $L_T$ that converges to zero, we have

$$\sup_{|\zeta_1 - \zeta_2| \leq L_T} ||V^2_T(\zeta_1) - V^2_T(\zeta_2)|| = o_p(1).$$

(14)

We now introduce a factor $T^{-1/2}$ that weights the contribution of the first-stage estimator in the kernel of the empirical process. For this, we choose $L_T^* = T^{1/2} L$ for a fixed positive number $L$. Let $V_T(\Delta) = M_T(\Delta) - E(M_T(\Delta))$, where $M_T(\Delta) = T^{-1/2} \sum_{t=1}^T m(w_t, \Delta)$, $m(w_t, \Delta) = x_t \psi(qv_t - T^{-1/2} x_t^T \Delta)$, and $\Delta$ is a $K \times 1$ vector. Since $V^2_T(\zeta) = V_T(T^{1/2} \zeta)$, by defining $\Delta_1 = T^{1/2} \zeta_1$ and $\Delta_2 = T^{1/2} \zeta_2$, the result in (14) becomes

$$\sup_{|\Delta_1 - \Delta_2| \leq L} ||V_T(\Delta_1) - V_T(\Delta_2)|| = o_p(1).$$

(15)

Setting $\Delta_1 = \Delta$ and $\Delta_2 = 0$ in (15), yields

$$\sup_{|\Delta| < L} ||M_T(\Delta) - E(M_T(0)) - \{E M_T(\Delta) - E M_T(0)\}|| = o_p(1).$$

(16)

Next, we show that $E(M_T(\Delta)) - E(M_T(0)) \to -q^{-1} Q_0 \Delta$ as follows. First, we note that

$$E(M_T(\Delta)) = E \left\{ T^{-1/2} \sum_{t=1}^T x_t \theta - x_t \int_{-\infty}^{t^{-1/2} \Delta} f_t(v|x_t) dv \right\}.$$

Therefore, we have

$$E(M_T(\Delta)) - E(M_T(0)) = -E \left\{ T^{-1/2} \sum_{t=1}^T x_t \int_0^{t^{-1/2} \Delta} f_t(v|x_t) dv \right\}$$

$$= -E \left\{ q^{-1} T^{-1} \sum_{t=1}^T x_t x_t^T \Delta F_1(q^{-1} T^{-1/2} \Delta | x_t) - F_1(0|x_t) \right\},$$

where $F_1(|x_t)$ is the conditional cdf of $v_t$. Let $G(\lambda) = q^{-1} T^{-1} \sum_{t=1}^T F_1(\lambda|x_t)x_t x_t^T \Delta$. Then, by the Mean-Value Theorem and the continuity in Assumption 3(ii), there exists $\xi_{T,t}$ between 0 and $q^{-1} T^{-1/2} \Delta$ such that $E(M_T(\Delta)) - E(M_T(0)) = -E \{G'(|\xi_{T,t}|)\} = -q^{-1} E \{T^{-1} \sum_{t=1}^T f_t(|\xi_{T,t}|x_t), x_t x_t^T \} \Delta$. We now examine the convergence of this term.

Let $Q_T = E \left\{ T^{-1} \sum_{t=1}^T f_t(\xi_{T,t}|x_t)x_t x_t^T \right\}$, $Q_0 T = E \left\{ T^{-1} \sum_{t=1}^T f_t(0|x_t)x_t x_t^T \right\}$ and consider the $(i,j)^{th}$ element of $|Q_T - Q_0 T|$, which is given by

$$|T^{-1} \sum_{t=1}^T E \left( \{f_t(\xi_{T,t}|x_t) - f_t(0|x_t)\} x_{ti} x_{tj} \right)|$$

$$\leq T^{-1} \sum_{t=1}^T E \left( |f_t(\xi_{T,t}|x_t) - f_t(0|x_t)| \ |x_{ti}| \ |x_{tj}| \right)$$

$$\leq L_0 T^{-1} \sum_{t=1}^T E \left( |\xi_{T,t}| \ |x_{ti}| \ |x_{tj}| \right).$$
for some constant $L_0$, where the first result is due to Minkowski’s inequality and Jensen’s inequality and the second result is obtained by the Lipschitz continuity in Assumption 3(ii). Next, we note that

$$T^{-1} \sum_{t=1}^{T} E \left( |x_{t}^{i}| \mid x_{t}^{i} \right) \leq q^{-1} T^{-3/2} \sum_{t=1}^{T} E \left( |x_{t}^{i} \Delta| \mid x_{t}^{i} \mid x_{t}^{j} \right)$$

$$\leq q^{-1} \| \Delta \| T^{-3/2} \sum_{t=1}^{T} E \left( |x_{t}^{i}|^3 \right)$$

$$\leq q^{-1} \| \Delta \| T^{-1/2} C \rightarrow 0$$

for a constant $C$, where the last inequality is obtained by Assumption 3(v). Since $Q_0 = \lim_{T \rightarrow \infty} Q_{0T}$, we have $E(M_T(\Delta)) = E(M_T(0)) \rightarrow -q^{-1} Q_0 \Delta$. QED.

**Proof of Proposition 1:** We define $\hat{\Delta}_0 = - (1 - q) T^{1/2}(\hat{\pi} - \pi_0 - B_\pi) + T^{1/2}(\hat{\Pi} - \Pi_0 - B_{\Pi}) \gamma_0$. We have $\hat{\Delta}_0 = O_p(1)$ because of Assumption 2. Then, Lemma 1 implies that

$$M_T(\hat{\Delta}_0) = M_T(0) - q^{-1} Q_0 \hat{\Delta}_0 + o_p(1),$$

(17)

where $M_T$ is defined Lemma 1. The term $q^{-1} Q_0 \hat{\Delta}_0$ is bounded in probability because $\hat{\Delta}_0 = O_p(1)$. Also, $M_T(0) = T^{-1/2} \sum_{t=1}^{T} x_t \psi_q(q_t) = T^{-1/2} \sum_{t=1}^{T} x_t \psi_q(v_t)$ because $q > 0$. Therefore, under Assumptions 1, 3(iv)-(v) and 4(i), $T^{-1/2} \sum_{t=1}^{T} x_t \psi_q(v_t)$ converges in distribution to a normal random variable by the CLT in Theorem 5.20 of White (2001). Therefore, we have

$$M_T(\hat{\Delta}_0) = O_p(1).$$

(18)

Next, we define $\hat{\Delta}_1(\delta) = H(\hat{\Pi}) \delta + \hat{\Delta}_0 = H(\hat{\Pi}) \delta - (1 - q) T^{1/2}(\hat{\pi} - \pi_0 - B_\pi) + T^{1/2}(\hat{\Pi} - \Pi_0 - B_{\Pi}) \gamma_0$ for $||\delta|| \leq L$, where $\delta \in R^{G+K_1}$ for some $L > 0$. Using Assumption 2 and Lemma 1, it is straightforward to show that

$$\sup_{||\delta|| \leq L} \|M_T(\hat{\Delta}_1(\delta)) - M_T(0) + q^{-1} Q_0 \hat{\Delta}_1(\delta)|| = o_p(1).$$

(19)

Before to reach the main part of the proof, we need one more result of stochastic equicontinuity. For this, we define $M_T(\delta) = H(\hat{\Pi}) M_T(\hat{\Delta}_1(\delta))$ and $||H(\hat{\Pi})||^2 = tr(H(\hat{\Pi}) H(\hat{\Pi})^T)$, which is $O_p(1)$ since $\hat{\Pi}$ converges to $\Pi_0 + B_{\Pi}$ that is finite.

We now use the argument between (A.7) and (A.8) in Powell (1983) to show that (18) and (19) imply that for some finite $L_2 > 0$

$$\sup_{||\delta|| \leq L_2} \|\hat{M}_T(\delta) - H(\Pi_0^0)' M_T(\hat{\Delta}_0) + q^{-1} Q_{zz}^{*} \delta\| = o_p(1),$$

(20)

where $Q_{zz}^{*} = H(\Pi_0^0)' Q_0 H(\Pi_0^0)$. The essence of the Powell’s argument is the following. Since $||H(\hat{\Pi})||^2 = O_p(1)$ and $||H(\hat{\Pi}) - H(\Pi_0)\|| = o_p(1)$, we have

$$\|\hat{M}_T(\delta) - H(\Pi_0^0)' M_T(\hat{\Delta}_0) + Q_{zz}^{*} \delta\|$$

$$\leq ||H(\Pi_0)|| \|M_T(\hat{\Delta}_1(\delta)) - M_T(0) + q^{-1} Q_0 \hat{\Delta}_1(\delta)|| + ||H(\hat{\Pi}) - H(\Pi_0^0)|| \|M_T(0) - q^{-1} Q_0 \hat{\Delta}_0\|$$

$$+ ||H(\hat{\Pi}) - H(\Pi_0^0)|| \{ ||H(\Pi_0)|| + ||H(\Pi_0^0)\| \} \|q^{-1} Q_{zz}^{*} \delta\| + ||H(\Pi_0^0)\|,$$

\footnote{For $q < 0$, we have $\psi_q(q_t) = - \psi_{1-q}(v_t)$. Therefore, $E(\psi_q(v_t)|x_t) = 0$ does not imply $E(\psi_q(q_t)|x_t) = 0$ in general, except for LAD estimators ($\theta = 1/2$) or symmetric distributions. This might be one reason why authors imposed symmetry of error terms, as in Chen (1988) and Chen and Portnoy (1990).}
which delivers the result by applying the sup-operator to both sides of the inequality above.

Next, we define \( \Delta = T^{1/2} (\hat{\alpha} - \alpha_0 - B_\alpha) \), where the expression for \( B_\alpha \) is given in the proposition. We wish to show that

\[
\tilde{M}_T(\Delta) = o_p(1). \tag{21}
\]

Note that

\[
\tilde{M}_T(\Delta) = H(\hat{\Pi})' M_T(\Delta_1(\hat{\Delta}))
\]

\[
= T^{-1/2} \sum_{t=1}^{T} H(\hat{\Pi})' x_t \psi(\theta) (q v_t - T^{-1/2} x_t' \hat{\Delta}_1(\hat{\Delta}))
\]

\[
= T^{-1/2} \sum_{t=1}^{T} H(\hat{\Pi})' x_t \psi(\theta) (q y_t + (1-q) \hat{y}_t - x_t' H(\hat{\Pi}) \hat{\alpha} + \hat{A}_t + \hat{B}_t)
\]

where

\[
\hat{A}_t = x_t' H(\hat{\Pi}) \alpha_0 - x_t' H(\Pi_0) \alpha_0 + x_t' \Pi_0' \gamma_0 - x_t' \hat{\Pi} \gamma_0
\]

and

\[
\hat{B}_t = x_t' [H(\hat{\Pi}) B_\alpha - (1-q) B_\pi + B_\Pi \gamma_0].
\]

First, we have that \( \hat{A}_t = 0 \) because \( x_t' H(\hat{\Pi}) \alpha_0 = x_t' \alpha_0 + x_t' \hat{\Pi} \gamma_0 \) and \( x_t' H(\Pi_0) \alpha_0 = x_t' \alpha_0 + x_t' \Pi_0' \gamma_0 \). Moreover, \( \hat{B}_t = 0 \) because of the definition of \( B_\alpha \). Since \( \hat{A}_t = 0 \) and \( \hat{B}_t = 0 \), it can be shown that

\[
T^{1/2} \tilde{M}_T(\Delta) = \left[ \frac{\partial S}{\partial \alpha} \right]_{\alpha = \hat{\alpha}} ,
\]

which is the vector of left-hand-side partial derivatives of the objective function in (5) evaluated at the solution \( \hat{\alpha} \). Therefore, we obtain the desired result in (21); i.e., \( \tilde{M}_T(\Delta) = o_p(1) \).

Next, let us show that \( \Delta = T^{1/2} (\hat{\alpha} - \alpha_0 - B_\alpha) = O_p(1) \). This will prove that \( B_\alpha \) is the asymptotic bias of \( \hat{\alpha} \). We can obtain \( \Delta = O_p(1) \) by using the argument in Lemma A.4 in Koenker and Zhao (1996). Similar arguments are in Jureckova (1977) and Hjort and Pollard (1999). To use Lemma A.4 in Koenker and Zhao (1996) and to obtain \( \Delta = O_p(1) \), we need to check the following conditions:

(i) \(-\delta' \tilde{M}_T(\lambda \delta) \geq -\delta' \tilde{M}_T(\delta) \) for \( \lambda \geq 1 \) and \( ||\delta|| \leq L_3 \) for some \( L_3 > 0 \),

(ii) \( ||H(\Pi_0)' M_T(\Delta_0)|| = o_p(1) \),

(iii) \( \tilde{M}_T(\Delta) = o_p(1) \),

(iv) \( Q_{zz}^* \) is positive definite.

Condition (i) is obtained by noticing that function \( h(\lambda) = \sum_{t=1}^{T} \rho_0(q v_t - T^{-1/2} x_t' H(\Pi) \lambda - T^{-1/2} x_t' \hat{\Delta}_0) \) is convex in \( \lambda \), and therefore that its gradient, \(-\delta' \tilde{M}_T(\lambda \delta) \) is non-decreasing in \( \lambda \). Condition (ii) comes from (18). Condition (iii) results from the first-order condition of the second stage, as we discussed above. Finally, condition (iv) is ensured by Assumptions 3(i) and 3(iii). Hence, by Lemma A.4 in Koenker and Zhao (1996), we have

\[
\Delta = T^{1/2} (\hat{\alpha} - \alpha_0 - B_\alpha) = O_p(1). \tag{22}
\]

Therefore, we can plug \( \Delta \) into (20) in place of \( \delta \) to obtain the following result:

\[
\tilde{M}_T(\Delta) - H(\Pi_0)' M_T(\Delta_0) + q^{-1} Q_{zz}^* \Delta = o_p(1). \tag{23}
\]

Note that the first term in (23) is \( o_p(1) \) because of (21). Hence, we have

\[
q^{-1} Q_{zz}^* \Delta = H(\Pi_0)' M_T(\Delta_0) + o_p(1) \tag{24}
\]

\[
= H(\Pi_0)' M_T(0) - H(\Pi_0)' q^{-1} Q_0 \Delta_0 + o_p(1), \tag{25}
\]

22
where the second equality comes from (17). By plugging the definition of $\hat{\Delta}_0$ and inverting $q^{-1}Q_{zz}$, we obtain
\[
T^{1/2}(\hat{\alpha} - \alpha_0 - B_\alpha) = Q_{zz}^{-1}H(\Pi_0^s)'(T^{-1/2} \sum_{t=1}^T x_t q \psi_q(v_t) + (1-q)Q_0 T^{1/2}(\bar{\pi} - \pi_0 - B_\pi) - Q_0 T^{1/2}(\bar{\Pi} - \Pi_0 - B\Pi)\gamma_0) + o_p(1),
\]
which completes the proof. QED.

Proof of Proposition 2: Let us decompose $B_\alpha$ as follows: $B_\alpha = \begin{bmatrix} B_{\alpha,1} \\ B_{\alpha,2} \end{bmatrix}$ where $B_{\alpha,1}$ is the vector of the $K_1$ elements of $B_\alpha$. We need to show that (i) $B_{\alpha,1} = (1-q)B_{x,1} - B_{\Pi,1}\gamma_0$, and (ii) $B_{\alpha,2} = 0_G$. First, we note that the definition of $B_\alpha$ is given by $B_\alpha = RQ_0\{(1-q)B_x - B\Pi\gamma_0\}$ in Proposition 1. Second, we decompose matrix $R$ as $R = \begin{bmatrix} R_1 \\ R_2 \end{bmatrix}$, where $R_1$ is the first $K_1 \times K$ submatrix and $R_2$ is the remaining $G \times K$ submatrix. We decompose matrix $Q_0$ as $Q_0 = [Q_1, Q_2]$ where $Q_1$ is the first $K \times K_1$ submatrix and $Q_2$ is the remaining $K \times K_2$ submatrix. Then, we have
\[
B_\alpha = \begin{bmatrix} R_1 \\ R_2 \end{bmatrix} [Q_1, Q_2] \begin{bmatrix} B_{\alpha,1} \\ B_{\alpha,2} \end{bmatrix} = \begin{bmatrix} R_1 Q_1 B_{\alpha,1} \\ R_2 Q_1 B_{\alpha,1} \end{bmatrix},
\]
where the second equality comes from the fact that $B_{\alpha,2} = 0_G$. Therefore, if we can show that (i) $R_1 Q_1 = I_{K_1}$, and (ii) $R_2 Q_1 = 0_{G \times K_1}$, then the proof will be completed. Because of the definition of $R$, the following identity holds.
\[
RQ_0 H(\Pi_0^s) = I_{K_1 \times G}. \tag{26}
\]
Let us decompose $\Pi_0^s$ as $\Pi_0^s = \begin{bmatrix} \Pi_{0,1}^s \\ \Pi_{0,2}^s \end{bmatrix}$, where $\Pi_{0,1}^s$ is the $K_1 \times G$ submatrix and $\Pi_{0,2}^s$ is the remaining $K_2 \times G$ submatrix. With this decomposition of $\Pi_0^s$, The left-hand-side of (26) is given by
\[
RQ_0 H(\Pi_0^s) = \begin{bmatrix} R_1 Q_1 & R_1 Q_2 \\ R_2 Q_1 & R_2 Q_2 \end{bmatrix} \begin{bmatrix} I_{K_1} & \Pi_{0,1}^s \\ 0_{K_2 \times K_1} & \Pi_{0,2}^s \end{bmatrix} = \begin{bmatrix} R_1 Q_1 & R_1 Q_1 \Pi_{0,1}^s + R_1 Q_2 \Pi_{0,2}^s \\ R_2 Q_1 & R_2 Q_2 \end{bmatrix}.
\]
Noting that the $(1,1)$-block is a $K_1 \times K_1$ submatrix and the $(2,2)$-block is a $G \times G$ submatrix, the identity in (26) delivers the desired results: (i) $R_1 Q_1 = I_{K_1}$, and (ii) $R_2 Q_1 = 0_{G \times K_1}$. QED.

Proof of Proposition 3: Replacing the asymptotic representation of the first-stage estimators and collecting terms in the asymptotic representation for the 2SQR($\theta, q$) with LS first-stage estimators gives
\[
T^{1/2}(\hat{\alpha} - \alpha_0 - B_\alpha) = MT^{-1/2} \sum_{t=1}^T S_t + o_p(1),
\]
where $M = R[I, -Q_0Q^{-1}]$ and $S_t = (q \psi_q(v_t), qv_t^* - u_t^*)' \otimes x_t$. Since $x_t^*, u_t, v_t$ are $\alpha$-mixing by assumption, and $S_t$ is a measurable function of $x_t^*, u_t, v_t$, it follows that $S_t$ is also $\alpha$-mixing. Next, $E(S_t) = 0$ by Assumptions 3(iv) and 4(ii). Finally, Assumption 4(i) provides all the moment conditions necessary to invoke Theorem 5.20 of White (2001). Hence, we have:
\[
V_T^{-1/2}T^{-1/2} \sum_{t=1}^T S_t \overset{d}{\rightarrow} N(0, I),
\]
where \( V_T = \text{var} \left( T^{-1/2} \sum_{t=1}^T S_t \right) \). Hence, the proof is completed. QED.

**Proof of Lemma 1:** With OLS first-stage estimators, we have \( \sigma_0^2(q) = aq^2 + 2bq + c \), where \( a = E \left[ f(0)^{-1} \psi (v_t) - v_t^* \right]^2 \), \( b = E \left[ (f(0)^{-1} \psi (v_t) - v_t^*) u_t \right] \) and \( c = E(u_t^2) \), which corresponds to a convex parabolic curve that attains its minimum at

\[
q^* = -\frac{b}{a} = \frac{E(v_t^* u_t^*) - f(0)^{-1}E(\psi(v_t)u_t^*)}{f(0)^{-2}(1 - \theta) + E(v_t^2) - 2f(0)^{-1}E(\psi(v_t)v_t^*)},
\]

which completes the proof. QED.

**Proof of the TLS case:** Since it is generated by censorship at two symmetric quantiles, the error term in the first step of the calculus of the TLS estimator can be written as

\[
\tilde{v}_t = \tilde{t}_v \begin{cases} 
F^{-1}(v_t) & \text{if } v_t < F^{-1}(\mu) \\
F^{-1}(v_t < F^{-1}(1 - \mu)) & \text{if } v_t < F^{-1}(1 - \mu) \\
0 & \text{otherwise}
\end{cases}
\]

This transformation of the initial error term \( v_t \) corresponds to the trimming that is performed by using quantile regressions before applying the least square estimator.

The terms with a negative sign in Assumption 3′′ is what remains from the condition \( E(\tilde{v}_t|v_{(i)}; j = 2, \ldots) = 0 \) that has not been cancelled, i.e. \( E(\tilde{v}_t) \). For the OLS estimator, this is \( (Ev_t, 0, \ldots, 0) \). For the TLS, this yields \( (Ev_t) + \mu(F^{-1}(\mu) + F^{-1}(1 - \mu)), 0, \ldots, 0) \), where \( t\_v_t = v_t I_{F^{-1}(\mu) < v_t < F^{-1}(1 - \mu)} \) is the truncated error term. Indeed, using the above formula for \( \tilde{v}_t \), we have

\[
E\tilde{v}_t = F^{-1}(\mu) P[v_t < F^{-1}(\mu)] + F^{-1}(1 - \mu) P[v_t < F^{-1}(1 - \mu)] + \int_{F^{-1}(1 - \mu)}^{F^{-1}(\mu)} v f_t(v) dv
\]

\[
= F^{-1}(\mu) F(F^{-1}(\mu)) + F^{-1}(1 - \mu) \{ 1 - F[v_t < F^{-1}(1 - \mu)] \} + E(t\_v_t),
\]

which gives the result: \( F^{-1}(\mu) + F^{-1}(1 - \mu) \mu + E(t\_v_t) \). QED.
Appendix B: Simulation Design

We base our simulations on a simultaneous equation system with two simple equations. The first equation, which is the equation of interest, contains two endogenous variables and two exogenous variables including a constant. Four exogenous variables are present in the whole system. The structural simultaneous equation system can be written

\[ \begin{bmatrix} y_t \\ Y_t \end{bmatrix} + \Gamma x_t = U_t, \]

where \( \begin{bmatrix} y_t \\ Y_t \end{bmatrix} \) is a 2 \times 1 vector of endogenous variables, \( x_t \) is a 4 \times 1 vector of exogenous variables with the first element equal to one. The error term \( U_t \) is a 2 \times 1 vector of error terms. We specify the structural parameters as follows:

\[ B = \begin{bmatrix} 1 \\ -0.7 \end{bmatrix}, \Gamma = \begin{bmatrix} -1 & -0.2 & 0 & 0 \\ -1 & 0 & -0.4 & 0.2 \end{bmatrix}. \]

The system is over-identified by the exclusion restrictions \( \Gamma_{13} = \Gamma_{14} = \Gamma_{22} = 0 \). Moreover, \( \begin{bmatrix} v & V \end{bmatrix} = U (B')^{-1} \).

The choice of the parameter values is led by the following considerations. Only moderate cross effects of the two endogenous variables are specified so that the endogeneity problem be interesting but not extreme. Identification restrictions and the degree of over-identification drive the occurrence of exogenous variables in the equations. Moderate, while non-negligible and comparable effects are allowed for these variables.

The error \( v \) in the reduced-form equations is generated so as to satisfy Assumption 3(iv):

\[ v = v^e - F_{v^e}^{-1}(\theta) \]

where \( v^e = \sigma(x_5t)w_t \), \( w_t \) is generated by using alternatively the distributions \( N(0,1) \), \( t(3) \) and \( LN(0,1) \) with autocorrelation coefficient \(-0.1\) and \( x_5t \) is generated from a distribution \( N(0,1) \) independently of other random variables and errors. Because we assume that \( x_5t \) is independent of \( w_t \) and \( w_t \) is iid, \( F_{v^e}^{-1}(\theta) = \sigma(x_5t)F_{w}^{-1}(\theta) \), where \( F_{w}^{-1}(\theta) \) is the inverse cumulative function of \( w_t \) evaluated at \( \theta \). The scale factor is \( \sigma(x_5t) = 1 + \delta x_5t \). We choose \( \delta = 0.05 \) under heteroskedasticity and \( \delta = 0 \) under iid. The errors \( V_j \) are generated in the same way, albeit without heteroskedasticity. Then, we draw the second to fourth columns in \( X \) from the normal distribution with mean \((0.5, 1, -0.1)'\), variances normalized to 1, \( cov(x_2, x_3) = 0.3, cov(x_2, x_4) = 0.1 \) and \( cov(x_3, x_4) = 0.2 \), where \( x_2, x_3 \) and \( x_4 \) are respectively the second, third and fourth components of \( x_t \). The correlations between the exogenous variables are neither extreme nor negligible. Given \( X, \begin{bmatrix} v & V \end{bmatrix} \) and \( \begin{bmatrix} \pi_0 \\ \Pi_0 \end{bmatrix} = -\Gamma'(B')^{-1} \), we generate the endogenous variables \( \begin{bmatrix} y & Y \end{bmatrix} \) by using the reduced-form equation:

\[ \begin{bmatrix} y \\ Y \end{bmatrix} = X \begin{bmatrix} \pi_0 \\ \Pi_0 \end{bmatrix} + \begin{bmatrix} v \\ V \end{bmatrix} \]
