Financing and advising with (over)confident entrepreneurs: an experimental investigation

Laurent Vilanova, Nadège Marchand, Walid Hichri

Abstract:

We test in the laboratory how entrepreneurs' skill perceptions influence the design of financing and advising contracts. Our theoretical framework proposes that selfconfident entrepreneurs prefer issuing debt whereas low self-confident ones prefer equity which induces strong investor assistance. The prevalence of overconfidence makes investors more reluctant to accept debt offers and constrains self-confident entrepreneurs to finance through mixed securities. Experimental results show that self-confident entrepreneurs issue more debt-like securities and receive less assistance. We also show that entrepreneurs learn not to offer pure debt and that initial ignorance of their own skills reinforces entrepreneurs' ability to learn through risky choices.

Abstract

We test in the laboratory how entrepreneurs' skill perceptions influence the design of financing and advising contracts. Our theoretical framework proposes that self-confident entrepreneurs prefer issuing debt whereas low self-confident ones prefer equity which induces strong investor assistance. The prevalence of overconfidence makes investors more reluctant to accept debt offers and constrains self-confident entrepreneurs to finance through mixed securities. Experimental results show that self-confident entrepreneurs issue more debt-like securities and receive less assistance. We also show that entrepreneurs learn not to offer pure debt and that initial ignorance of their own skills reinforces entrepreneurs' ability to learn through risky choices.

1 Introduction

In the face of high failure rates of new ventures and the low return of entrepreneurial activity (Moskowitz and Vissing-Jorgensen 2002), it is often argued that entrepreneurs exhibit too much confidence in their own abilities, in future outcomes and in their judgments (Busenitz 1999, Cooper et al. 1988, Palich and Bagby 1995). Whereas entrepreneurial overconfidence is viewed as the main reason of excess entry (Camerer and Lovallo 1999), little is known on the precise effect of overconfidence on some other key entrepreneurial decisions, such as the choice of start-up financing. The question is all the more important that the economics and finance literature suggests that financing choices significantly affect new ventures' performance. Accordingly, a common view is that venture capitalists provide valuable managerial inputs and increase the ex post performance of their portfolio firms (Kaplan and Strömberg 2004). Reconciling entrepreneurial overconfidence and the recourse to venture capital is however far from being obvious. For example, founders who overestimate their personal abilities may neglect resource needs of their venture and reject valuable social ties and/or external advice critical to success (Hayward et al. 2006). Following this idea, it is questionable whether overconfident entrepreneurs would be interested by the advising activity of venture capitalists.

The main objective of the paper is to test experimentally whether and how entrepreneurial self-confidence (possibly overconfidence) affects the choice of financing and advising contracts. Our game, inspired from the theoretical model of Vilanova (2013), considers the interaction between individuals that possess an investment project (henceforth, entrepreneurs) and investors. The probability of project success depends on the entrepreneur's skills, which depends within game on the entrepreneur's rank on a general quiz like in Camerer and Lovallo (1999). After the quiz, and without feedback on his quiz performance, each entrepreneur proposes a contract to the investor that specifies the repartition of outcomes in case of success and in case of failure. If the investor accepts the offer, the contract is signed and

the investor sets the intensity of his advising activity (which is non contractible). This advising activity increases the project's probability of success in the sole case when the entrepreneur's performance to the quiz is low, i.e. when the entrepreneur is poorly skilled.

This simple framework permits to capture an entrepreneur's basic choice of financing, i.e., bank financing vs. venture capital financing (de Bettignies and Brander 2007, Winton and Yerramilli 2008). Banks' claims are poorly sensitive to the venture's performance and banks are often presented as passive investors that bring little advice to the firm. In contrast, venture capitalists are active investors that bring advising services to their portfolio firms. They also receive more "equity-like" securities that give them higher upside in case of success. According to Vilanova (2013), the trade-off between these two forms of financing should depend on the entrepreneur's skill perceptions. A high self-confident entrepreneur should naturally prefer to issue debt because (i) debt financing gives him a higher payoff in case of success, a state of nature that he considers as highly probable (ii) he believes that his own talent is sufficient to succeed and is, hence, reluctant to pay for a venture capitalist's advising activity. In contrast a low self-confident entrepreneur should prefer to issue an equity-like security that gives the investor more incentives to exert an advising effort. This suggests the existence of a natural separating equilibrium where high self-confident entrepreneurs issue debt securities and where low self-confident ones issue equity securities. The prevalence of entrepreneurial overconfidence - i.e. the fact that some high self-confident entrepreneurs overestimate their skills - could however affect the equilibrium contracting choices. Basically, if investors suspect entrepreneurial overconfidence, high self-confident entrepreneurs could be denied debt financing and could be obliged to issue securities that have more equity-features than their preferred choice. At the extreme, i.e. when overconfidence is highly pervasive, all the entrepreneurs (high- and low self-confident ones) could issue the same security and a pooling equilibrium might dominate.

To our knowledge, our paper is the first to experimentally test how entrepreneurial (over)confidence affects equilibrium financing and advising contracts. Existing empirical studies (either in the laboratory or in the field) have focused on the behavioral consequences of overconfidence without considering the interactions with providers of resources. Along this line of inquiry, extent research has demonstrated that overconfident individuals are more likely to select risky projects and to overinvest (e.g. Camerer and Lovo 1999, Malmendier and Tate 2008). Also highly-confident individuals tend to discount advice (Tost et al. 2012) and are less likely to seek for advice (See et al. 2011). Another stream of research has examined experimentally optimal contracting either in an adverse-selection context (Cabrales and Charness 2005) or in a principal-agent context (Anderhub et al. 2002). To our knowledge, however, there exists no empirical evidence on optimal contracting with potentially overconfident agents.

Our experiment also addresses the dynamics of contracting. Over time, entrepreneurs can revise their initial self-views, learn their true skills and adapt their contractual offers. During the first periods, entrepreneurs should set their offers according to their perceived skills and, because these perceptions might be upwardly biased, investors should apply an “overconfidence premium”. In the final periods, entrepreneurs should be more informed about their true type and contractual offers should reflect their actual skills rather than their initial perceived skills. If learning takes place, final periods should give rise to a separating equilibrium where high-skilled entrepreneurs and low-skilled entrepreneurs opt for debt securities and equity securities respectively. In our game, however, the convergence towards this separating equilibrium is not guaranteed. First, convergence could be hampered by the fact that entrepreneurs insufficiently adjust their beliefs to new information and/or by the fact that investors are doubtful about the entrepreneurs’ capacity to learn their true skills. Second, consistent with the learning dynamics observed in the ultimatum game (Cooper et al. 1988, Slonim and Roth 1998), high-skilled entrepreneurs

could learn not to offer securities that give investors a small fraction of outcomes, that is, pure debt securities. Hence, how optimal contracting evolves over time and experience is an open question that deserves further investigation.

The rest of the paper is the following. Section 2 presents the theoretical background. Section 3 addresses the experimental design. Section 4 presents the findings and we conclude in Section 5.

2 Theoretical background

We experimentally test a simplified version of the model proposed by Vilanova (2013).¹

The model considers two players: F (the financier) and E (the entrepreneur). E needs 80 to finance a project but has no initial wealth. In order to finance his project, E must obtain funds from F. We denote by r , the rate of return required by F in order to finance E.

Project success depends on two parameters: E's managerial skills and the advising (or supporting) effort provided by F. E might possess high skills (type H) or low skills (type L). It is common knowledge that there is an equal proportion of type-H and of type-L in the economy. When F finances E but provides no advice ($M = 0$), the project managed by a type-H entrepreneur generates a final outcome 200 with probability 1 whereas the project managed by a type-L yields a final payoff 50 with probability 1. The intensity of F's advising activity (M) can however increase the chance of success of a venture managed by a type-L entrepreneur. We capture this value-adding effect of advising by considering that a project managed by a type-L entrepreneur is successful (yields 200) with probability M and fails (yields 50) with probability $(1 - M)$. Obviously, advising is costly and we denote by c_M the cost of

¹Vilanova (2013) proposes a double moral hazard model where the entrepreneur and the investor both exert effort after contracting and where both efforts affect the venture's final payoff. In this article, and in order to simplify the game for participants, we consider instead that only the investor's (advising) effort affects the venture's chance of success.

advising effort for F . We assume that this cost is an increasing and convex function in M .

The order of moves is the following:

1. Player E offers a contract C_i to player F . This contract specifies the allocation of cash flow rights depending on the project's final return. The contract proposes to pay $G_i\%$ to player F in case of success and $P_i\%$ to player F in case of failure. We restrict here the set of feasible contracts to four contracts (see Figure 1). These contracts can be distinguished on two dimensions: the equity component of the security offered to player F (or equivalently, the incentive package proposed to the financier) measured by $G_i\% - P_i\%$; the downside protection provided to the financier measured by $P_i\%$. We interpret payment schemes where financiers receive a low incentive package and a high downside protection as debt-like contracts. In contrast, contracts with a high incentive package and a low downside protection are interpreted as equity-like contracts. This leads us to interpret C_1 as an equity contract, C_2 as a debt contract, C_3 as a mixed security with a debt-like orientation and C_4 as a mixed security with an equity-like orientation.

Insert Figure 1 about here

2. Player F accepts the offer or not. This decision depends on the offered contract, on player F 's perceptions about player E 's skills (p_H^E) and on player F 's required return (r).

3. If the offer is accepted, the project is implemented and F decides on the intensity of his advising activity (M). The advising effort of player F is not contractible. We use a "mini-game" where we restrict the intensity of advising effort to four values, $M \in (0, 0.25, 0.5, 0.75)$. Table 1 summarizes the four values of M and their associated costs c_M . Notably, c_M is an increasing and convex function in M .²

²The values of c_M in Table 2 were computed by assuming that $c_M = kM^2/2$ with $k = 160$ when $M = 0.25$ and $k = 150$ for $M = 0.5$ and $M = 0.75$.

Insert Table 1 about here

Obviously, the choices made by E and F depend on their respective beliefs about the actual skills of the entrepreneur. We denote by $p_H^E \in [0, 1]$, E's subjective belief that he is H. The higher is p_H^E , the more E is *self-confident*. Symetrically, F will decide to accept the security offered by E and will choose the intensity of his advising activity according to $p_H^F \in [0, 1]$, which denotes F's belief that E is of type H.

In this setting, the contract C_i offered by E should be the solution to the following maximization problem:

$$\underset{G_i\%, P_i\%}{Max} p_H^E(1 - G_i\%)200 + (1 - p_H^E) [M(1 - G_i\%)200 + (1 - M)(1 - P_i\%)50] \quad (1)$$

$$M \in \arg \max \{p_H^F G_i\%200 + (1 - p_H^F) [M G_i\%200 + (1 - M) P_i\%50] - c_M\} \quad (2)$$

$$p_H^F G_i\%200 + (1 - p_H^F) [M G_i\%200 + (1 - M) P_i\%50] - c_M - (1 + r)80 \geq 0 \quad (3)$$

where (1) represents E's expected payoff, (2) is for F's IC constraint and (3) is for F's participation constraint.

As obvious here, there exist multiple solutions depending on the precise value of p_H^E , p_H^F and r . A crucial point is that p_H^F is partly contingent on the contract offer made by E. When setting his beliefs on E's skills, F accounts for the facts that (i) E's offer might convey information about E's self-confidence (i.e. p_H^E) and, (ii) even if E's offer perfectly reveals p_H^E , F might estimate that E's offer is an imperfect signal of E's true quality and might set $p_H^F < p_H^E$ if he suspects entrepreneurial overconfidence.

2.1 Results of the static game

In the static model presented above, where learning effects are absent, the main propositions are the following:

Proposition 1 (F's advising effort): *F advising effort (M) increases in the equity component of the offered contract, i.e. $(G_i\%200 - P_i\%50)$, and decreases in F's perceptions of E's skills, i.e. p_H^F .*

This is direct by computing the FOC of (2). The optimal advising effort of the player F is such that $c'_M = (1 - p_H^F)(G_i\%200 - P_i\%50)$.

Proposition 2 (E's preferences): *Highly-confident Es, i.e., those with high p_H^E , prefer to issue a security with a strong debt component (C_2 optimally or C_3). In contrast, self-unconfident Es (i.e., those with low p_H^E) prefer to issue a security with a strong equity component (C_1 optimally or C_4).*

The intuition is straightforward. From (1), it is direct that an extremely self-confident E (with $p_H^E = 1$) believes that F's advising is useless. He is also prone to abandon all the project's cash flows in case of failure (i.e. to offer a contract with $P_i\% = 1$). Then, he prefers to issue a security with a strong debt component that limits the intensity of investor advising effort. In contrast a low self-confident entrepreneur (i.e. a player E with low p_H^E) prefers intensive advising (high M). Because F's advising effort cannot entirely compensate low entrepreneurial skills (i.e. $M < 1$), he is also less prone to sacrifice his payoff in case of failure than a high self-confident entrepreneur and prefers to set $P_i\% < 1$. All in all, a low self-confident entrepreneur prefers to issue a security with a strong equity component.

Proposition 3 (Separating equilibrium when players E have accurate beliefs about their skills): *When players Es beliefs are unbiased (presumably in final periods), that is when entrepreneurs accurately estimate their skill level:*

- *High self-confident/ High-skilled Es should offer a debt contract (C_2), player F should accept the offer and should set $M = 0$.*
- *Low self-confident/ Low-skilled Es should issue equity (C_1), player F should accept and should set $M = 0.75$.*

If entrepreneurs have accurate self-beliefs, a separating equilibrium should arise. Consider the case of a player E of type H. If accurate, this player should have beliefs $p_H^E = 1$ and should offer a security with $P\% = 1$. Observing this offer, F should induce that E is of type H ($p_H^F = p_H^E = 1$) and should set his advising effort to $M = 0$. Then, the optimal contract is such that $G_i\%200 = (1 + r) 80$ and $P_i\%50 = 50$, which resembles to contract C_2 in our “mini-game”. Consider now the reverse case when the entrepreneur has low self-confidence and when both players share the same beliefs, i.e. $p_H^F = p_H^E = 0$. In this case, both players agree on the necessity of a high advising effort. The low self-confident E has no incentive to mimick a high self-confident E by issuing C_2 because this would destroy player F’s incentive to exert effort. He is then better off by issuing a security with a strong equity-component, which corresponds in our setting to C_1 . When observing C_1 , the financier should revise his beliefs to $p_H^F = 0$ and should set his advising effort to $M = 0.75$.³

Proposition 4 (Optimal contracting when players E have available information but are suspected of being overconfident): *When players E have available information about their skills but financiers suspect the presence of overconfident Es, players F should reject debt offers C_2 . High self-confident Es should rather issue mixed securities (C_3 or C_4), financiers should accept and should exert an intermediate effort ($M = 0.25$ or 0.5).*

In our model, a suspicion of unrealistic optimism exists when $p_H^F < p_H^E$. Obviously this suspicion affects the choice of financing and advising contracts. Consider for instance the case of a high self-confident entrepreneur, $p_H^E = 1$. By prediction 3, we know that when entrepreneurs’ beliefs are unbiased a high self-confident/high-skilled E prefers issuing a debt contract with $G\% = \frac{(1+r)I}{X^g}$ and $P\% = 1$ that induces no advising effort ($M = 0$). This debt financing contract is accessible if the financier’s

³If E offers C_1 and $p_H^F = 0$, c'_M is equal to 150, the highest possible value in our mini-game. Because c_M is an increasing and convex function in M , F will exert the highest possible effort, i.e. $M = 0.75$.

beliefs are similar to the ones of the entrepreneur ($p_H^F = p_H^E = 1$). In contrast, if player F suspects the presence of overconfident Es, i.e. if $p_H^F < p_H^E \equiv 1$, a high self-confident E has no other choice but to issue a security which provides a higher upside to the financier (with $G\%X^g > (1+r)I$) and that induces a strictly positive advising effort ($M > 0$). This contract that combines debt and equity components resembles more to a mixed security (C_3 or C_4) than to pure debt.⁴

Proposition 5 (Pooling equilibrium when players have no information on Es' skills): *When players have no available information on entrepreneurial skills ($p_H^F = p_H^E = 0.5$), players E should issue a mixed security (either C_3 or C_4), players F should accept and should set an intermediate advising effort ($M = 0.25$ or 0.5).*

In certain contexts, Es could have poor information about their skills. Within our game, this corresponds to a case where entrepreneurs have no private information about their entrepreneurial skills and set $p_H^E = 0.5$, which corresponds to the proportion of type-H in the economy. In our model, this configuration precludes any (pooling) equilibrium with C_2 (because player's F participation constraint would not hold) or with C_1 (because player E is better off with a mixed security that offers a lower equity component to player F).

2.2 Learning and dynamic contracting

A crucial point is that our theoretical framework does not address how players' E beliefs evolve over time. When learning opportunities exist, that is, when players E can learn their true type through experience, the behavior of both players might differ from the ones described above. How contract offers and advising efforts evolve

⁴Formally speaking, whether Es with different self-confidence (those with high p_H^E vs those with low p_H^E) separate or pool depends on the fraction of overconfident Es. If overconfidence is moderate, Es with high p_H^E can still signal their high self-confidence by issuing a security with more debt features than the one issued by Es with low p_H^E . If, instead, overconfidence is high, all players E (those with high p_H^E and those with low p_H^E) should issue the same mixed security (see Vilanova 2013). Also, in the latter case where a pooling equilibrium arises, the optimal contract (either C_3 or C_4) also depends on r , i.e. player's F required return.

over time is however an open question.

If learning occurs, the base-line prediction is that players should converge towards the separating equilibrium described in Proposition 3. During the first periods, Es should set their offers according to their perceived skills and, because these perceptions might be upwardly biased, Fs should apply an overconfidence “premium”. In particular, this suspicion of optimism could lead to systematic rejections of pure debt contracts (C_2) in early rounds. In the final periods, players E should have updated their self-beliefs and should be more informed about their true type. Hence, contractual offers in late rounds should reflect their actual skills rather than their perceived skills and the separating equilibrium described in Proposition 3 should prevail.

Proposition 6 (Rational learning): *Over time, players should converge towards the separating equilibrium described in Proposition 3 in which high-skilled Es offer pure debt securities (C_2), low-skilled Es offer pure equity securities (C_1) and where Fs accept to invest.*

The speed of convergence towards this separating equilibrium obviously depends on players’ capacity to implement strategies that reveal Es’ true skills. In other terms, learning opportunities are not entirely exogeneous and partially depend on players’ actions. In the multi-period version of the game, there exists a straightforward strategy for revealing the true skills of Es rapidly. This strategy consists, for Es, to propose a pure debt security in the first period (C_2) and, for Fs, to accept this offer and to set $M = 0$. If these strategies are implemented, observing the project outcomes at the end of the first period perfectly reveals Es’ true skills, with success associated to a type-H entrepreneur and failure associated to a L-type entrepreneur. Afterwards, equilibrium contracting should be similar to the one arising when players E are perfectly accurate about their skills (see Prediction 3). In sum, entrepreneurs who are uncertain about their true skills could rapidly learn their skills by implementing a “learning through risky choice” strategy similar to the one

described by Köszegi (2006).

Proposition 7 (Speed of convergence and learning through risky choice):

When players are uncertain about Es' skills, there exists a strategy profile that permits to reveal Es' true skills at the end of the first period. This profile consists for Es to propose a pure debt security in the first period (C_2) and, for Fs, to accept this offer and to set $M = 0$. Such a strategy profile should accelerate convergence towards the separating equilibrium described in Proposition 3.

Laboratory evidence suggests, however, that players might not converge towards the separating equilibrium described in Proposition 3 after obtaining experience. Accordingly, experimental results in the ultimatum game typically show that “proposers” rarely make small offers, and that “responders” often reject small offers (Cooper et al. 2003, Slonim and Roth 1998). Because a pure debt security (C_2) gives the financier a small fraction of project outcomes in success, these results suggest that, in our framework, pure debt offers might be made rarely, and might be frequently rejected when made. Explanations provided by reinforcement models of learning (Roth and Erev 1995) could apply here. In particular, the frequency with which high-skilled Es offer C_2 could diminish over time because of the high rejection rate of C_2 by Fs within first periods. Because of this high rejection rate, Es could offer less frequently C_2 in subsequent rounds even if type-H entrepreneurs might have learnt their type. In other words, high self-confident entrepreneurs (whether accurate or not) and high-skilled ones could learn not to offer pure debt securities.⁵

Proposition 8 (Reinforcement models of learning): *Convergence towards the separating equilibrium described in Proposition 3 does not occur because high self-confident Es and/or type-H Es learn not to offer pure debt security (C_2). The frequency of an offer C_2 should decrease over time and Fs should frequently reject this offer when made.*

⁵An alternative reason for the non convergence towards the separating equilibrium where type-H Es offer C_2 is that financiers could estimate that the profit sharing associated with this security is unfair (see for example Rabin 1993).

3 Experimental design

The experiment is divided in four main treatments and each treatment is divided into two successive parts: a first part that aims to determine the skills of players E (either H or L-type) and to elicit skill perceptions; a second part where players E and F interact conformely to the financing and advising game described above.

The first part starts with a quiz composed of 10 questions dealing with general culture. After answering the questions, players are asked to evaluate their own relative performance. More precisely, participants are asked what probability they assign belonging to the above-median players (their relative performance). At the end of this first part, a computer program assigns a role (F or E) to each player to the session. Players E are classified according to their relative performance on the quiz (in skill rank treatments). A player E is classified as a H-type if he belongs to the 50% of players E that have the highest number of correct answers on the quiz and is classified as a L-type if he belongs to the 50% of players E that have the least correct answers on the quiz. Players are told whether they are F or E, but players E don't know whether they are of type H or L. Obviously, each player E has his own belief (that could be true or false) about his ranking in the group and hence on his type. Notably, this belief relates to one's confidence in his relative abilities (Camerer and Lovo 1999). In addition to the information concerning their role (F or E), we communicated to all players additional information on Es' beliefs at the group level in two of the five treatments. More precisely, we communicated the number of high self-confident Es and the number of type-H Es among those who expressed high self-confidence.

The second part of the experiment starts with a matching protocol where a computer program randomly matches a player E with a player F. We used a stranger design, wherein matching changes in the beginning of each period and a player never deals with the same individual during the experiment. After the matching is made, the game described in the preceding section begins. Sequentially: (1) Each player

E offers a contract C_i ($G_i\%.200$, $P_i\%.50$) to player F; (2) each player F accepts the offer (and transfers 80 to player E) or rejects the offer (no transfer); (3) if the offer is accepted, F chooses his advising effort M . Table 2 summarizes the one-period payoff of each player. Participants were told their own payoff at the end of each period.

Insert Table 2 about here

Our experiment consists of five treatments with four tested parameters (see Table 3).

The first tested parameter is the rule used to rank Es, that is, the way Es are assigned to the type-H or type-L category. In treatments 1 to 3, Es are ranked according to their relative performance on the quiz (skill rank condition) and are classified as type H if they are above-median performers. In contrast, E's type is set according to a chance device in treatments 4 and 5 (random rank condition). If rational, each E should assign a 50% probability for being a type-H in the random rank condition. This distinction between skill-rank and random-rank conditions aims to capture whether inflated self-beliefs affect the equilibrium behavior of entrepreneurs and financiers. Indeed, we expect Es to be more self-confident and possibly more overconfident in the skill rank condition (Camerer and Lovo 1999).

The second tested parameter concerns the additional information given to all players about self- and overconfidence on a group-level at the end of the first part of the experiment (after the quiz and before the choice of contracts). In treatment 2, participants received no additional. In the treatments 1 and 3, players were informed on the percentage of highly self-confident Es and on the percentage of overconfident Es. Such an information should affect the securities C_i offered by Es and the subsequent decisions of Fs (acceptation and advising effort). More specifically, we expect that the equilibrium described in Proposition 4 should be more likely when players receive information indicating that a substantial part of players E are overconfident. Indeed, in this case, Fs should be more reluctant to accept pure debt securities (C_2)

and highly self-confident Es should rather propose mixed securities. Note also that players did not receive additional information in random rank treatments (i.e. treatments 4 and 5) as participants should then rationally assign a 0.5 probability for a given E to be a type-H.

The third parameter tests the effect of the difficulty of the task in the skill rank condition. We used a difficult quiz in treatment 3 and an easy quiz in treatments 1 and 2. By manipulating quiz difficulty, we intended to generate variations in Es' self-confidence and overconfidence. This was motivated by the typical finding that individuals are more self-confident in their relative performance and are more likely to be overconfident in easy tasks rather than in difficult tasks (Hoelzl and Rustichini 2005, Moore and Healy 2008).

The last parameter is about the assignment of E's skills over periods. In the majority of our treatments, Es kept their type H or L unchanged over the 10 rounds of each session. In these treatments, learning opportunities existed and Es had the possibility to learn their true skills over time. This permits to test whether players converge (or not) towards the separating equilibrium described in Proposition 3, as discussed in Propositions 6 to 8. In treatment 5, Es potentially changed their type at each period as a new random affectation of type (type-H or type-L) was made at each round. This implies that Es had no opportunities to learn their true skills in treatment 5. All in all, the conditions of treatment 5 are similar to those described in Proposition 5. Hence, in this treatment, we expected Es and Fs to implement the strategies described in Proposition 5 at each round.⁶

The following table summarizes the variation of the tested parameters in the different treatments:

⁶Importantly, the same individuals participated in treatments 4 and 5. More precisely, each participant played 20 rounds. During the first 10 periods (treatment 4), players E kept their type H or L over time. During the 10 subsequent periods (treatment 5), there was a new random affectation of type H or L to players E in each period. Hence, participants in treatment 5 were more experienced than those operating in other treatments. For the other treatments, participants played only 10 rounds.

Insert Table 3 about here

The experiment was run in May 2010 at laboratory GATE in Lyon. Players were drawn from a database composed of more than 1600 persons. They were asked to participate to a computerized game. We used REGATE-NG as software and run four sessions. A number of 20 players participated to each session, which makes a total of 80 persons for the whole experiment. In the beginning of each session, players are affected randomly to each computer. They were asked not to communicate during all the experiment. Each session was composed of 10 periods and lasted about one hour, and players were paid in cash and in a private way at the end of the session according to a rate that converts points into euros according to the rate 1 euro for each 100 points.

4 Findings

4.1 Skill perceptions

We first analyse how participants evaluate their own performance after the quiz, i.e. at the end of the first part of the experiment.

As a preamble, we checked that the quiz used in treatment 3 is more difficult than the one used in the three other treatments. With the easy quiz, the average percentage of correct answers was 49% in Treatment 1, 54% in Treatment 2, and 53% in Treatment 4. These values show a constant level of difficulty of the quiz for all groups in these “easy” treatments (52% of correct answers in average). In treatment 3, the average percentage of correct answers was only 33,5% (cf. first line of Table 4). This confirms that the quiz used in treatment 3 is more difficult and can be used as a parameter to test the effect of the level of task difficulty.

Insert Table 4 about here

The first measure of skill perceptions is participants' self-confidence, i.e. their perceptions of belonging to the above-median players (i.e. of being type H). In our game a participant is self-confident when he sets a probability higher or equal to 0.5 of belonging to above-median players. Over all treatments, 62.5% of players E are highly self-confident (believe that they are H), which suggests overconfidence at the group level. Accordingly, Figure 2 shows that 27.5% of players E are overconfident (believe they are H although their true type is L) after the quiz vs. 57.5% are realistic and 15% are underconfident (believe that they are L although they are H).

Considering the effect of quiz difficulty on the skill perceptions of players E, Table 4 indicates that players E are more likely to be highly self-confident and overconfident in easy treatments (Treatments 1, 2 and 4) than in difficult treatments (Treatment 3). This is consistent with findings in psychology which show that people tend to overestimate their relative performance in easy tasks (Moore and Healy 2008).

Insert Figure 2 about here

4.2 Financiers' acceptance decision and advising effort

The financier's decision to invest, i.e. to transfer funds, strongly depends on the contractual offers made by players E (Table 5). The propensity of players F to invest is strictly increasing in the equity-like orientation of the offered security. At the two extremes, players F accept an offer C_2 (Debt) only 37.4% of the time and in contrast almost always accept an offer C_1 (Equity) (95.7% of the time). Also, consistent with prediction 2, players F exert more advising effort with equity-oriented securities than with debt-oriented securities. The average advising effort is 0.51 for contract C_1 (Equity) and of only 0.13 for contract C_2 (Debt). The advising effort of financiers is moderate with mixed securities, and as expected, is higher with contract C_4 (Mixed Equity) than with contract C_3 (Mixed Debt).

Insert Table 5 about here

In analyzing the behavior of player F, we face a sample selection bias as the dependant variable “M” (the intensity of advising effort) is observed only if player F has accepted the offer made by player E (Figure 3).

Insert Figure 3 about here

For a given F-player i , y_{i2} is not observed unless y_{i1} equals one. Therefore, the robustness of those observations is checked using a bivariate probit model with a sample selection bias that allows to estimate the probability of two simultaneous events, the acceptance and the advising decisions (Greene 1997). The results are given in Table 6.

In a first step, the decision to accept an offer is specified as a latent variable y_{i1}^* , denoted:

$$y_{i1} = \begin{cases} 1 & \text{if } y_{i1}^* > 0 \\ 0 & \text{otherwise} \end{cases}$$

It is assumed linear in the observables : $y_{i1}^* = X_{i1}\beta_1 + u_{i1}$ where X_{i1} includes two set of dummies. On the one hand, we capture our treatment effects through four dummies namely: treatments 1 to 5, except treatment 2 that is used as our benchmark. Treatment 5 corresponds to the last 10 periods of treatment 4, where the type of E (H or L) is distributed randomly after each period. On the other hand, we set dummies for the contract offers C_1 , C_2 and C_4 (C_3 is used as a benchmark).

In a second step, the decision to exert an advising effort conditional on the contract offer being accepted is specified as a latent variable, y_{i2}^* , denoted:

$$y_{i2} = \begin{cases} 1 & \text{if } y_{i2}^* > 0 \\ 0 & \text{otherwise} \end{cases}$$

We also assume that the latent variable is linear in the observables : $y_{i2}^* = X_{i2}\beta_2 + u_{i2}$ where X_{i2} includes three variables, namely *overconfidence* treated as a dummy equal to 1 if player E is overconfident and 0 otherwise, and self-confidence which is set equal to 1 if player E is highly self-confident. The last variable captures the equity-orientation of the contract, and takes a value of 1 for contract C_2 (debt), 2 for C_3 (Mixed debt), 3 for C_4 (Mixed equity) and 4 for C_1 (Equity).

Finally, we use the Huber-White variance estimator to allow the fitting of our model that may contain heteroscedastic residuals because of the likely correlation between the observations associated to a same individual.

Table 6 reports the results of the two-steps probit regression.

Insert Table 6 about here

Results show that player F’s decision to accept the offer, i.e., to invest, relies strongly on the type of contract offered by player E: C_1 (Equity) and C_4 (Mixed Equity) are more likely to be accepted than C_3 (Mixed Debt), whereas C_2 (Debt) is less likely to be accepted than C_3 . Also, the financier propensity to exert an advising effort is increasing in the equity orientation of the security offered.

Acceptation decisions also differ according to treatments. For skill treatments (T1 to T3), players F are less likely to invest when they have feedback on the group level self-confidence and overconfidence of players E (Treatments 1 and 3 vs. Treatment 2). This could account for the fact that, in the absence of feedback indicating that players E have biased self-views, financiers suppose that players E are well calibrated (no self-deception). This is consistent with the “presumption of calibration” hypothesis advanced by Tenney et al. (2008) and Sah et al. (2013). In contrast, players F are more reluctant to invest when they receive explicit information that indicates the presence of miscalibrated Es. It is also noticeable that Fs are more reluctant to invest in Treatment 5 where ranking is random and changes every period, a context in which learning is impossible.

4.3 Entrepreneurs' contract offers

Table 7 shows that players E frequently offer mixed securities. Contract C_1 (equity), the first best choice for low-skill Es, is rarely offered even if this contract is almost always accepted and generates the highest advising effort from player F (see Tables 5 and 6). The debt contract (C_2) is more frequently offered than C_1 (equity) but is still less proposed than mixed securities (C_3 and C_4), particularly in last rounds. Prima facie, the predominance of mixed securities could be explained by the suspicion of overconfidence. On the one side, some players E could be reluctant to offer the contract C_1 because they are overconfident and hence believe that the advising effort of F is unnecessary. Also, the fact that debt (C_2) is less often proposed than mixed securities in last rounds could be due to the reluctance of financiers to accept a debt contract when they suspect the presence of overconfident entrepreneurs. This interpretation finds some support in the fact that the contract C_2 is often rejected by financiers (see Tables 5 and 6). Overall, mixed contracts dominate as predicted by the suspicion of overconfidence.

Our theoretical framework hypothesizes that the type of contracts proposed by entrepreneurs should depend both on their initial perceived skills (this effect should be more pronounced during the first rounds) and their actual skills. Table 7 illustrates the effect of actual skills and initial perceived skills on the offer of contracts (only for skill treatments T1, T2 and T3) and also illustrates the dynamics of contract choices by contrasting the first five periods (“first rounds”) and the last five periods (“last rounds”).

Insert Table 7 about here

Table 7 reveals that the proportion of pure debt offers (C_2) is slightly higher for high- than for low self-confident entrepreneurs (31% vs. 27%). Partial support for Proposition 2, which predicts that high- and low self-confident should be more

likely to issue pure debt and pure equity respectively during the first rounds of the experiment, is also provided by the fact that low self-confident Es proposed relatively more often pure equity (C_1) during the first rounds (17% of the offers vs. 9% for highly self-confident entrepreneurs). The learning effect, that stipulates that type-H entrepreneurs should converge towards debt-like securities (C_2 and C_3) and type-L ones towards equity-like securities (C_1 and C_4), finds some support in the results that 73% of high-skill Es opt for a debt-like security in the last periods of the experiment (37% choose C_2 and 36% choose C_3) and that 71% of low-skill Es opt for an equity-like security (20% choose C_1 and 51% choose C_4). However, the convergence occurs mainly through the issuance of mixed securities instead of pure securities, which departs from the “rational learning” hypothesis formulated in Proposition 6.

A possible interpretation for the absence of convergence towards “pure” contracts C_1 and C_2 across periods can be advanced. The fact that the frequency with which high-skill entrepreneurs offer C_2 (their first-best contract) diminishes across periods might be explained by the high rejection rate of C_2 by financiers during the first periods. In the subsequent rounds, players E offer less frequently the contract C_2 even if H-type entrepreneurs might have learnt their type throughout periods. This is obviously not consistent with rational learning, since we predicted in Proposition 6 that debt (C_2) could be rejected in the first periods (when players F might presume overconfidence among players E) but should be more frequently accepted once entrepreneurs know precisely their skills (supposedly in the final periods). All in all, although entrepreneurs’ skills seem to affect the choice of extreme contracts (C_1 and C_2), the fact that both skilled and unskilled entrepreneurs converge towards offers of mixed securities across time suggests that our participants were unable to interpret the outcomes of the first periods to determine entrepreneurs’ actual skills.

In order to evaluate the robustness of entrepreneurs’ contract offers, we run a multinomial logistic regression. This allows us to investigate the relation between the

contract’s choice of players E and independent variables related to their individual characteristics (self-confidence, overconfidence, the time when their type is revealed) or structural variables such as rounds. In our game, a player E has to choose one of the four available contracts, the general form of the multinomial logit model can be written as:

$$prob(Y = j | X) = \frac{e^{X\beta_j}}{1 + \sum e^{X\beta_k}} \text{ for } j=1,2,3,4.$$

The β are the parameters of the model and X is a vector of player characteristics. All specifications are normalized with respect to C_2 . We also consider a variable quoted `reveal_H` that accounts for the fact that players E have information that permits them to infer that they are of type H.⁷ Once informed, the dummy variable `reveal_H` is set to one.

Insert Table 10 about here

Results presented in Table 8 confirm that highly self-confident Es are less likely to offer pure equity than pure debt. The negative coefficients of the variable “`Reveal_H`” indicate that players E are less likely to offer securities with an equity component than pure debt when they have enough information to conclude that they are of type H. Overall, these results are consistent with the idea that Es with high-skill perceptions prefer to issue pure debt (C_2) and provide support to Proposition 2. Although high-skill Es offer preferentially pure debt when they are in position to know their own skills, the positive coefficients of the variable “`round`” show, however, that players E tend to abandon contract C_2 over time in favor of other contracts, which suggests that reinforcement models of learning could apply here (see Proposition 8). Finally, it is noteworthy that E’s overconfidence has no

⁷In our game, players E have this information when the following sequence of moves has been observed: player E has offered contract C_2 , F has accepted the offer and has set $M = 0$, player E received 0.

effect on the contract offered. This may be due to the dual nature of overconfident Es who are jointly highly self-confident and low-skill. While their high self-confidence might lead them to offer pure debt during the first rounds, overconfident Es may have incentives to switch towards more equity-oriented securities (in particular to C_4 as suggested in Table 7) once they realize that they are low-skill.

Collectively, the results of our experiment suggest that high initial self-confidence increases the likelihood of pure debt contract offers during the first rounds. What happens in the following rounds depends on the reactions of players F to these initial offers. When these offers are rejected (which occurs frequently according to Table 5), highly self-confident Es cannot revise their self-beliefs and tend to switch towards mixed securities C_3 and C_4 in order to increase the likelihood of their offer being accepted. This is consistent with the idea that highly self-confident entrepreneurs learn not to offer pure debt securities (Proposition 8). If pure debt offers are accepted by players F during the first rounds, highly self-confident Es are more likely to learn their true type. Those who learn that they were realistic, i.e. type-H entrepreneurs, are more likely to persist in offering C_2 (cf. the negative coefficients of `Reveal_H` in Table 8). In contrast, those who discover that they were overconfident, i.e. type-L entrepreneurs, switch towards a more equity-oriented security C_4 (see Table 7).

4.4 Differential payoffs across treatments and over time

A final consideration is about the payoffs of participants. Figure 4 suggests that high-skill Es gain more in T4, the treatment where their skills are initially set by a random device and are fixed across rounds. This is at first glance surprising because players E should be more able to evaluate their skills and should perform better in skill treatments (T1, T2, and T3).

Insert Figure 4 about here

In order to validate this effect, we run a random effects GSL regression where the dependent variable is the average per-period payoffs of player i (see Table 9). The regression is run on 80 individuals ($N=80$) observed during 10 periods. As illustrated in Table 9, player E earns significantly less than F, mainly because of the absence of endowment in the first stage of the game. Also, payoffs are higher when player F accepts the contract offered by E and when player E has high skills (H-type). Another important finding is that treatments have no impact on participants' payoffs, except for type-H entrepreneurs who have significantly higher payoffs in treatment 4 than in other treatments.

Insert Table 9 about here

Notably, the higher payoffs of type-H entrepreneurs in the random skill treatment 4, whereby player E is more likely to offer a debt contract C_2 and player F is more likely to accept this offer than in skill treatments (see Table 5), seem consistent with the “learning through risky choice” strategy described in proposition 7 (Kőszegi 2006). In other words, players E may have implemented in this treatment a deliberate research strategy, which consists in playing C_2 in the first rounds in order to discover their type. Indeed, in a dynamic setting, playing C_2 initially induces little advising effort from player F and permits to conclude very quickly if player E is H or L. One might wonder, however, why players did not implement such a profitable strategy in skill treatments. We leave this discussion for the next section.

5 Discussion and conclusion

Our objective was to test experimentally optimal contracting and advising when entrepreneurs are potentially overconfident.

The findings presented in the above section validate several of our theoretical predictions derived from Vilanova (2013). First, it appears that investors (players F) are more likely to finance entrepreneurs (players E) and are more likely to provide advising when they hold equity-oriented securities. Also, highly self-confident entrepreneurs - who believe that they are sufficiently skilled to succeed without external advice - are more likely to finance through debt-oriented securities, whereas those with low self-confidence finance preferentially their venture with equity-oriented securities. Consistent with our prediction that entrepreneurs' biased self-views might impede signaling, we also found that separation between high-skilled entrepreneurs and low-skilled ones did not prevail and that at equilibrium a significant fraction of entrepreneurs issue mixed securities. Interestingly, this experimental results fits well with the observation that venture capital investors often hold securities that combine equity and debt features (Kaplan and Strömberg 2003, 2004).

Our experiment also produces some interesting findings about the dynamics of optimal contracting. Surprisingly, we find very weak evidence of learning over time. Some reasons might be advanced. Notably, it appears that debt contracts were more frequently offered by entrepreneurs during the first rounds than in the last rounds of the experiment. This stands in direct contradiction with the base-line prediction that high-skill entrepreneurs should learn their true type over time and should converge towards debt financing in the last rounds of the game. A possible reason why highly-skill entrepreneurs do not converge towards debt financing is that financiers tend to largely reject debt offers in the first rounds. While this rejection is natural in the first rounds (because financiers might suspect overconfidence among entrepreneurs), the paradox is that offers of debt contracts durably disappeared. In sum, we find that an equilibrium emerges where pure debt contract are definitively selected out even if rational learning suggests that experienced and high-skill entrepreneurs should

converge towards this type of financing. Although not consistent with rational learning, this finding is concordant with the predictions of reinforcement models of learning (Cooper et al. 2003, Roth and Erev 1995, Slonim and Roth 1998). All occurs as if entrepreneurs learn not to offer pure debt, by inferring that early rejections of debt offers make highly probable that financiers will continue to reject debt in the future.

The finding that high-skill entrepreneurs obtain higher gains when they are initially more uncertain about their type (i.e., when their type is set according to a chance device rather than to their relative performance on the quiz) is also a priori striking. Notably, our experiment shows that subjects were more likely to implement a rational “learning through risky choice” strategy (that consists for the entrepreneur to offer debt, and for the financier to accept the offer and to provide a low advising effort) and, hence, entrepreneurs were more likely to learn their true type rapidly when entrepreneurs had less precise self-beliefs at the beginning of the game. A potential explanation of why this strategy was implemented less often in treatments where the entrepreneur’s type was set according to his relative performance may be found in the literature on information avoidance. According to Köszegi (2006), agents derive ego utility from positive views about the self and don’t want new information that may taint their positive self-image. In our experimental setting, the revelation of the entrepreneur’s type is more likely to threaten self-image when type depends on (relative) skills rather than on a random device.⁸ Therefore, and consistent with our findings, entrepreneurs, particularly those who are highly confident in their abilities, should be more reluctant to take the risk of learning their true type and to implement a “learning through risky choice” strategy in skill rank condition than in random rank condition. While providing further support to the ego utility argument of Köszegi (2006) (see also Eil and Rao, 2011), this result also suggests an-

⁸In the skill rank condition, the revelation that he is a type-L signals to the entrepreneur that he is an above-median performer in the quiz. In contrast, such revelation only signals “bad luck” in the random rank condition.

other channel through which entrepreneurs' highly confident self-beliefs might hurt the performance of new ventures. Not only, these beliefs may lead individuals to neglect the quality of their competitors (Camerer and Lovo 1999), but also they may prevent them from learning their true abilities through experience. Accordingly, our findings suggest that initially ignorant entrepreneurs (presumably novice ones) may implement more effective strategies than experienced ones. In contrast, experienced entrepreneurs may develop rigid and possibly overconfident self-beliefs over time, a result consistent with the heuristics and biases research, which argues for an increased risk of overconfidence among experts (Yates et al. 1991). It is important to note, however, that in our two-players setting the absence of "ego utility" motive is not sufficient to explain the adoption of the "learning through risky choice strategy" in the random rank condition. To be effective, i.e., to reveal the entrepreneur's true type, a debt offer must be followed by a specific sequence of moves by the financier (acceptation of the offer and low advising effort). The fact that financiers were more likely to adopt this sequence of moves in random rank treatments may indicate that financiers anticipate that entrepreneurs are more prone to revise their self-beliefs and to learn their true type when ego utility is not at stake.

Obviously, this paper is only a first step to explain the dynamics of optimal contracting between potentially overconfident entrepreneurs and potentially advising investors. In particular, further work should try to disentangle the extent to which the dynamics of entrepreneurs' contract offers reflects the evolution of their self-beliefs over time and/or their anticipation of investors' responses.

Figure 4: Average one-period payoff by type of player E and over time
For each type of player and for each treatment, we report the average one-period period during the first rounds (1 to 5) and the last rounds (6 to 10)

	Coefficient	(Std. Err.)
Treatment 1	-4.228	(-1.14)
Treatment 3	-1.109	(-0.30)
Treatment 4	-2.203	(-0.54)
Contract accepted by F	30.48***	(11.60)
Player E	-60.06***	(-13.80)
Overconfidence	10.06	(1.22)
Self-confidence	-7.262	(-1.16)
Player E of type H	29.05***	(4.67)
Player E of type H in treatment 4	14.40**	(1.97)
Constant	63.05***	(18.09)
N		800
ρ		0.0223
σ_u		5.016
ρ_e		33.23

Table 9: The determinants of players' gains
Treatments 1 to 4 are dummy variables with treatment 2 set as the benchmark (see. Table 3 for a full description of the treatments).

	All rounds				First rounds (1 to 5)				Last rounds (6 to 10)			
	C1 Equity	C2 Debt	C3 Mixed Debt	C4 Mixed Equity	C1 Equity	C2 Debt	C3 Mixed Debt	C4 Mixed Equity	C1 Equity	C2 Debt	C3 Mixed Debt	C4 Mixed Equity
All entrepreneurs	12%	30%	27%	31%	12%	35%	28%	25%	12%	25%	27%	38%
Low-skill (L-type)	20%	19%	19%	42%	20%	26%	21%	33%	20%	12%	17%	51%
High-skill (H-type)	4%	41%	36%	21%	4%	44%	35%	17%	3%	37%	36%	24%
Low self-confident	15%	27%	29%	29%	17%	37%	25%	20%	13%	17%	32%	37%
High self-confident	10%	31%	26%	33%	9%	34%	30%	28%	10%	29%	23%	38%

Table 7: Contract offers according to Es' true and perceived skillsThe table includes the offers made in all treatments except T5

	C1 (Equity)	C3 (Mixed Debt)	C4 (Mixed Equity)
Overconfidence	1.019 (0.673)	-0.102 (0.405)	-0.138 (0.409)
Self-confidence	-1.682** (0.587)	-0.347 (0.329)	-0.229 (0.335)
Round	0.261*** (0.071)	0.232*** (0.058)	0.342*** (0.058)
Reveal_H	-0.560** (0.186)	-0.308 *** (0.060)	-0.446 *** (0.072)
Constant	-1.277** (0.412)	-0.607* (0.321)	-1.090** (0.337)
N	400		
Log-likelihood	-478.815		
$\chi^2(\cdot)$	106.40		
Prob> $\chi^2(\cdot)$.000	

Table 8: Multinomial logistic regression for analyzing contract offers with . Standard deviations in parentheses. (***) Significant at the 0.01 level; (**): significant at the 0.05 level; (*) significant at the 0.1 level.

The debt contract (C_2) is the base outcome and dependent variables are dummies for self confidence and overconfidence. The reveal_H variable is set to one after a subject learnt his H-type by implementing the “learning through risky choice strategy”, otherwise it is equal to zero. Round refers to period 1 to 20.
