Communication and Commitment with Constraints in International Alliances

Raghul S Venkatesh†

July 23, 2019

Abstract

An informed and an uninformed agent both contribute to a joint coordination game such that their actions are substitutable and constrained. When agents are allowed to share information prior to the coordination stage, in the absence of commitment, there is full information revelation as long as constraints are not binding. The presence of binding constraints results in only partial revelation of information in equilibrium. The most informative equilibrium is strictly pareto dominant. Allowing for limited commitment strictly increases (ex ante) welfare of both agents. I completely characterize the optimal commitment mechanism for the uninformed agent. Finally, I apply the theoretical results to the problem of information sharing and binding agreements in international alliances.

Keywords: asymmetric information, cheap talk, commitment, strategic substitutes

---

*I am thankful to Sebastian Bervoets, Suzanne Bijkerk, Yann Bramoulle, Antonio Cabrales, Rahul Deb, Francoise Forges, Navin Kartik, Francesco Squintani, and seminar participants at Aix-Marseille University, Maastricht University, Delhi School of Economics, Erasmus School of Economics, Indian Statistical Institute (New Delhi), University of Warwick for useful comments and suggestions. I thank Aix-Marseille School of Economics for the Postdoctoral Fellow Research Grant and providing other financial support.

1 Introduction

In international alliances, member countries jointly make decisions in the presence of information asymmetry. They share private information and pool resources in order to achieve common objectives (e.g., collective defense, intelligence sharing, peacekeeping). For example, the principles of effective sharing of information and mutual commitment to work together have been central tenets of the NATO (see, e.g., Petersson, 2015; Wittmann, 2009). In a similar vein, more recently, the EU nations have initiated the Permanent Structured Cooperation (PESCO) agreement that aims at creating a collective defense policy. Achieving these objectives however usually involves coordination of actions between the member countries. The defining features of such coordination is that the actions of members are (imperfectly) substitutable and there are constraints (e.g. fiscal, military/personnel) on the available action choices.

To achieve coordination, alliances usually organize protocols based on communication (e.g., via diplomatic channels) to exchange private information between the members. When action constraints are not binding, it is possible for members to share information and coordinate efficiently. The incentive problem arises when an informed party is constrained by the set of actions available. In this case, it exacerbates the incentives of an informed member to misrepresent their private information in order to induce a higher action from the uninformed one. The constraints therefore affect countries’ capacity to contribute and coordinate efficiently. An important question that arises in this context is how do constraints on actions affect the nature of communication.

Alternatively, alliance members could resort to ex ante commitment contracts (e.g., through binding agreements) that specify decision rules that they can agree upon and commit to. However, when there are multiple decision-makers it is unclear as to what the optimal rules of commitment — or ex ante contracts — are. Further, whether there is any value of commitment — to binding agreements — in alliances is salient from a policy perspective.
To analyze these questions, this paper introduces a novel class of coordination games between two agents with one-sided asymmetric information, strategic substitutability in actions, and constraints on the action set. I analyze two forms of decision-making for this underlying coordination game. The first, *simultaneous protocol*, is based purely on *communication* (cheap talk à la Crawford and Sobel, 1982) with simultaneous decision-making and no commitment. The second, *commitment protocol*, resembles the classical *delegation problem* (Holmström, 1984) and models one-sided ex ante *commitment* with sequential decision-making.

The novelty of the model is that the coordination game is *aggregative*\(^1\) in nature (see, e.g., Jensen, 2010, Acemoglu and Jensen, 2013). From a theoretical standpoint, the paper offers two main contributions. First, it introduces a Bayesian version of an aggregative game and merges it with the vast literature on strategic communication. Second, the paper models limited commitment (see, e.g., Bester and Strausz, 2001; Krishna and Morgan, 2008) in which only the uninformed agent commits to a binding (contractible) decision rule while the informed agent’s action is *non-contractible*. The paper therefore also bridges the literature on communication with coordination motives and contracting with imperfect commitment. The model generates three main sets of results. They can be stated as follows:

- There is a *negative* relationship between constraints and communication, and, a *positive* relationship between communication and welfare. That is, lesser constraints imply greater credibility in information transmission and more information translates to higher welfare. The result sheds light on the importance of contributing to alliances. Specifically they carry both an *informational* effect (reduces constraints) and a *welfare* effect.

\(^1\)An aggregative game is one in which each players’ payoff is a function of their own strategy and a common aggregator function. The aggregator function itself can be represented as additively separable functions of each agents’ strategies. See also Corchon (1994) and Dubey, Haimanko, and Zapechelnyuk (2006).
• The optimal commitment contract exhibits an intuitively simple threshold feature. The uninformed agent minimizes miscoordination losses up to a threshold state conditional on providing the necessary informational rents to the informed agent. Beyond this, the actions of both agents are capped and unresponsive to any information.

• The value of commitment is positive for both agents. Further, these gains are increasing when constraints are more binding and when both agents have higher conflicts of interests. The result provides an ex ante utilitarian rationale for binding commitments within an alliance.

The setup of the model is the following. Each agent has a coordination function that generates an output based on the actions of both agents. The concavity property of the underlying utility function implies that there is an unique first best level of the coordination function corresponding to each state of the world, and these values are different for the two agents due to conflicting interests. Each agent’s coordination function itself is increasing, twice continuously differentiable, and concave in the actions of both agents. Crucially, the marginal impact of each agent’s action is higher on their own coordination function compared to the other agent’s coordination function.

Given this formulation, the coordination function is aggregative and the underlying game is Bayesian aggregative. The primitives directly imply that the coordination function exhibits imperfect substitututability in the actions of the agents. The first theorem establishes the existence and uniqueness of pure strategy equilibria in actions for the Bayesian aggregative game. Specifically, the result utilizes tools developed in the aggregative games literature (see, e.g., Acemoglu and Jensen, 2013) and reformulates them to the Bayesian game setup. The key intuition driving the result is the underlying aggregative property of the coordination function and imperfect substitutability feature of the preferences.²

²Given the uniqueness of actions for any set of beliefs between the agents, it is then possible to fully
Adding communication to the Bayesian aggregative game results in communication equilibria that are *threshold* in nature. In the threshold equilibria, the informed agent communicates truthfully only up to a certain threshold state and pools all information beyond. When the informed agent does not suffer from binding constraints on actions, all private information is communicated in equilibrium and agents take actions as if there were perfectly informed. This further leads to full efficiency for both agents. The intuition is that in the absence of any constraints, both agents can take actions such that the joint coordination function for each agent corresponds with their first best levels, thereby precluding the need to misrepresent information. However, full information revelation breaks down in the presence of binding action constraints and there is some loss of information in equilibrium. The reason is that with binding constraints the informed agent finds it optimal to pool information at the top and induce a higher action from the uninformed agent. Since the informed agent also takes an action post communication, the agent can use her private information on the pooling interval to her benefit.

Given the multiplicity of communication equilibria in the model, it is imperative to compare their welfare properties. Surprisingly, the communication equilibria exhibit an intuitive pareto ordering - the more informative threshold equilibrium is ex ante pareto dominant. This implies that welfare of both agents is monotonically increasing in the amount of information revealed. The intuition is as follows. When more information is revealed, both agents achieve first best levels of coordination for a greater measure of types. Further, under the most informative equilibrium the pooling message induces a higher expected action from the uninformed agent. Since the informed agent has discretion in choosing her actions on the pooling interval accordingly, this implies that

---

3The threshold equilibria are similar to those derived by Kartik, Ottaviani, and Squintani (2007), and Kartik (2009). In both these papers, there is exaggerated communication in equilibrium which is in contrast to the truthful messaging equilibria characterized in this paper.

4There are other hybrid equilibria from communication that are in some sense subsumed by the threshold equilibria. They bear some semblance in structure to the central pooling equilibria in the work of Bernheim and Severinov (2003). See Proposition 1.
the informed agent’s utility is strictly better off on the pooling interval. This novel feature provides greater flexibility to the informed agent and allows for better coordination of the agents’ actions. It minimizes the inefficiency from under-provision (over-provision) for the informed (uninformed) agent, thereby improving welfare of both agents.

An important feature of the threshold equilibria is that it introduces miscoordination in agents’ actions due to informational asymmetries on the pooling interval. This results in inefficiencies on the pooling interval for both agents. Agents could instead rely on ex ante commitments to mitigate this inefficiency. In international alliances, for example, countries commit to binding agreements that specify mutually agreed upon rules of engagement. To capture this feature, I analyze a commitment protocol in which both agents agree to an ex ante contract where the uninformed agent commits to a communication dependent incentive compatible decision rule. The informed agent, on the other hand, decides on the information to communicate and subsequent (non-contractible) action after observing the decision rule of the uninformed agent. Notice that this is similar to the optimal delegation problem (Alonso and Matouschek, 2008) except that there is an additional informed decision-maker whose action is not contractible.

Since there is limited commitment, the informed agent, depending on the contracted commitment rule, can decide what information to reveal and then subsequently what action to take. This adds a layer of complexity to the commitment problem faced by the uninformed agent. Since the revelation principle is applicable, the uninformed agent’s problem is twofold: i) to choose an action rule that satisfies the informed agent’s non-contractibility constraint; and ii) to minimize the inefficiencies from coordination, conditional on satisfying the incentive compatibility conditions.

Trivially, the informed agent mimics the actions of the simultaneous protocol up to the most informative threshold. Beyond this, the optimal commitment rule exhibits two key features. The uninformed agent minimizes coordination losses by ensuring that the informed agent always takes the maximal action. This implies the uninformed
agent contributes only the residual action required to satisfy the informed agent’s IC constraint. Further, the uninformed agent caps actions beyond a (higher) threshold of information, meaning that the informed agent’s informational rent is capped beyond this threshold.\footnote{Without this capping, the uninformed agent would end up providing first best levels to the informed for all possible states, which would be equivalent to full delegation as in Dessein (2002). This form of full delegation is never optimal for the uninformed agent in this paper, similar to the result of Krishna and Morgan (2008).} By committing to an ex ante decision rule, the uninformed agent incentivizes the informed agent to reveal more information in a way that benefits both agents.

Finally, I consider a simple parameterized uniform-quadratic setting which captures all the features of the model. I provide closed form characterizations of the communication and commitment thresholds, the welfare of agents under the two protocols, and the welfare gains from commitment for both the agents. Several interesting insights emerge from the analysis of the parameterized model. First, the informational threshold for truthful communication and the commitment threshold are both increasing in the upper bound of the action set of the informed agent. Second, the welfare of agents under both the protocols can be represented as a simple increasing function of the communication threshold. That is, any increase in the upper bound of the action set translates into more truthful communication and therefore higher welfare for the agents. Interestingly, the gains from commitment is decreasing in this parameter, but increases when both agents have more conflicting interests.

In Section 8 I discuss the main insights of the model in light of the recent developments that have focused attention on the importance of contributing to alliances. For example, the US leadership has urged the European bloc of countries to contribute their ‘fair share’ towards NATO.\footnote{“What seems to be clear, however, is that the Obama Administration does not want to lead NATO in the charismatic or traditional way that the US used to do. That has also been manifested in the discussion about the burden sharing within the alliance; that the European members must step up both concerning the leadership of the alliance in European affairs, and concerning actual defense spending.” - p.165, Petersson, 2015} The closed form solutions provide key insights in understanding why such issues are critical for international alliances. When a country con-
tributes more, their communication carries greater credibility and miscoordination losses are reduced. This in turn improves efficiency and increases welfare of partnering countries. Another important implication is that binding agreements between countries are pareto improving in an ex ante sense. By committing to different possible contingencies, countries that rely on information from others can reduce miscoordination and target their actions better. The gains from such commitments are actually higher when the action constraints are greater and when countries are more conflicted in their preferences over the final outcomes. Intuitively, my findings suggest that countries with greater divergence in interests have the most to gain from committing to binding agreements.

**Related Literature**

This paper extends and contributes to the vast theoretical and applied literature of that studies communication in interdependent environments. The role of communication with strategic complementarities in actions have been widely studied and applied to varied settings (e.g. Alonso, Dessein, and Matouschek, 2008; Baliga and Morris, 2002; Dessein and Santos, 2006; Hagenbach and Koessler, 2010; Rantakari, 2008). Barring Alonso (2007), who considers a principal-agent setting in which an uninformed principal controls the decision rights and actions of the two players are either strategic complements or substitutes, none of the other papers have looked at incentive problems when the nature of coordination is such that both players’ actions are substitutable.

The literature on delegation (Holmstrom, 1978) has delved into the question of optimal commitment by an uninformed Principal. Alonso and Matouschek (2008) characterize the necessary and sufficient conditions for interval delegation to be optimal under quadratic loss utility functions. Amador and Bagwell (2013) generalize this result for a broader class of welfare functions and also allow for money burning feature.\(^7\) Melumad Also relevant is the paper by Ambrus and Egorov (2017) who study a perfect commitment contracting problem with both money burning and monetary transfers feature.
and Shibano (1991) characterize a deterministic commitment rule for the uninformed receiver in a standard cheap talk game. The optimal commitment rule in my work, though deterministic, considers the case of two decision makers and limited one-sided commitment. The optimal mechanism resembles the interval delegation result in that the uninformed agent provides a cap on actions but the model allows for non-contractible actions (imperfect commitment) by the informed agent. In this regard, it is similar in taste to Bester and Strausz (2001) who study an imperfect commitment problem without transfers, and Krishna and Morgan (2008) who look at contracting with imperfect commitment and monetary transfers. However, in contrast to these papers, I model a problem in which both agents are decision-makers and there is limited commitment in the sense that the informed agent’s action is non-contractible.\textsuperscript{8}

This paper is also related to the work on communication and commitment by Forges, Horst, and Salomon (2016) and Forges and Horst (2018). They look at ex ante commitment contracts that are followed by communication of one-sided private information. The difference is that while they concentrate on two player games with no interdependencies, this paper focuses on coordination games with action substitutability. This apart, in their work the commitment imposes a stronger interim and ex-post individual rationality constraint, which is absent in my setup.

The rest of the paper proceeds as follows. In Section 2, I present a simple example to show the main intuition driving the results. Section 3 outlines the basic model and proves equilibrium existence. Section 4 presents all the communication equilibria and their efficiency properties. In Section 5 I characterize the optimal commitment mechanism and Section 6 derives all the results in the uniform quadratic setting. Section 7 includes a discussion of the results in the context of international alliances. Section 8 considers possible extensions and Section 9 provides concluding remarks.

\textsuperscript{8}In contrast, both Bester and Strausz (2001) and Krishna and Morgan (2008) study a problem where the uninformed Principal takes two decisions, one of which is contractible and the other, not.
2 An Example

Consider a joint task to be executed by an uninformed agent $A_1$ and an informed agent $A_2$ (without loss of generality). $A_2$ perfectly observes signal about the state of the world $\theta$, drawn from an uniform distribution $[0, 1]$. The information is soft and $A_2$ communicates its private information by sending a cheap talk message $m(\theta)$ to $A_1$. Upon communication, both $A_1$ and $A_2$ take actions that affects both their payoffs. Let the utility functions be the following:

$$U^1 = - \left[ \left( \frac{x_1 + \eta x_2}{1 + \eta} \right) - \theta \right]^2$$

$$U^2 = - \left[ \left( \frac{x_2 + \eta x_1}{1 + \eta} \right) - \theta - b \right]^2$$

Observe that both players take actions that contribute to the project and these actions are substitutable in that $\frac{d^2 U_i}{dx_1 dx_2} < 0$, where $\eta \in (0, 1)$ captures the degree of substitutability. Finally, the two players face constraints in that $x_i$ has a domain $[-a, a]$. When $A_2$ truthfully reveals the true state of the world, i.e. $m(\theta) = \theta$, the two players solve the following best responses:

$$A_1 : x_1 = (1 + \eta)\theta - \eta x_2$$

$$A_2 : x_2 = (1 + \eta)(\theta + b) - \eta x_1$$

To simplify the exposition, let $b = \frac{2}{5}$ and $\eta = \frac{1}{2}$. The actions after truthful messaging are given by: $x_1^* = \theta - \frac{2}{5}$, $x_2^* = \theta + \frac{4}{5}$. Notice immediately that full information revelation is possible if $a \geq \frac{9}{5}$. This is because $A_2$ is able to reveal truthfully the highest type $\theta = 1$, and $x_2^*(1) = \frac{9}{5}$. This way, $A_2$ achieves first best. On the other hand, when $a < \frac{4}{5}$, no information can be credibly revealed by $A_2$.

---

9Suppose say $a = \frac{2}{5}$. Then the constraint is binding for all types. $A_2$ can inflate her signal in order to induce $A_1$ to allocate more. To see this, instead of $m(0) = 0$, say inflated message is $m(0) = \frac{2}{5}$. Then,
Figure 1: When $a \geq \frac{9}{5}$, the action constraints are not binding for $A_2$, resulting in full information revelation. On the other hand, when $a \in (\frac{4}{5}, \frac{9}{5})$ there is only partial revelation of information.

Finally, when $\frac{4}{5} < a < \frac{9}{5}$, $A_2$ has an incentive to reveal some information. To see this, let $a = 1$. Then, for any $\theta \in [0, \frac{1}{5}]$, $A_2$ reveals the state truthfully since her optimal action is within the domain of available actions (in this case $x^*_2(\frac{1}{5}) = 1$). But, for any $\theta > \frac{1}{5}$, $A_2$ cannot sustain a truthful messaging strategy since the constraints are binding for $A_2$ (i.e. $x_2 = 1$). Then the optimal action for $A_1$ is according to its best response function, which is $x_1 = \frac{3}{2} \theta - \frac{1}{2}$. This cannot be an equilibrium since $A_2$ gets a payoff of $U_2 = -\left(1 + \frac{1}{2}(\frac{3}{2} \theta - \frac{1}{2}) - \theta - \frac{2}{5}\right)^2 \neq 0$ where $\frac{1}{2} + \frac{1}{2}(\frac{3}{2} \theta - \frac{1}{2}) < \theta + \frac{2}{5}$ for $m = \theta > \frac{1}{5}$. This implies there is under-allocation from $A_2$’s perspective if it reveals the truth. Therefore, $A_2$ has an incentive to exaggerate its information in order to induce the other agent to play a higher action. This precludes separation beyond $\theta = \frac{1}{5}$. In fact, all types above this cutoff send a pooling message, $m_p$. Therefore, there is at most a partially revealing equilibrium in which $A_2$ is truthful (separates) in the range $\theta \in [0, \frac{1}{5}]$ and pools for $A_1$ best responds by allocating $x_1^* = \frac{2}{5}$. $A_2$ then contributes $x_2^* = \frac{3}{5} - \frac{1}{5} = \frac{2}{5}$. That is, by inflating her information the informed agent induces a higher action from $A_1$ whilst achieving first best. However this incentive to misrepresent means that messages do not carry credibility in equilibrium. $A_2$ can never credibly reveal any information to $A_1$ and therefore communication is rendered ineffective.
\( \theta \in (\frac{1}{5}, 1] \) by sending the same message, \( m_p. \)

The example suggests a novel trade-off for information transmission with substitutability and action constraints. The ability to truthfully reveal information depends on the actions available to the informed player. The informed agent \( A_2 \) is able to provide more information as the action set available is bigger. For the same reasons, when constraints are binding, there is an incentive to inflate private information and extract more actions from the uninformed agent \( A_1 \).

3 The Model

Consider a joint project between two agents \( I = \{1, 2\} \). The payoff from the project is dependent on state \( \theta \in \Theta \) and the actions of both agents. The state \( \theta \in \Theta \) is distributed according to a cdf \( F \) and a corresponding density \( f \) with full support. Agent \( A_2 \) receives a perfectly observable private signal about the state \( \theta \) while agent \( A_1 \) is uninformed. The set of possible actions available to the agents is constrained and given by \( x_i \in V \subseteq \mathbb{R}^+ \), where the set \( V \) is closed and compact with \( \inf(V) = k, \sup(V) = \bar{k} \), and \( k, \bar{k} \in \mathbb{R}^+ \). Each agent’s utility is given by \( U(\phi^i(x_i, x_{-i}), \theta, b_i) \), where \( \phi^i(.) \) is the agent-specific joint action function (henceforth coordination function). The coordination function \( \phi^i(\cdot) \) depends on agent \( i \)'s action \( x_i \), as well as the action of the other agent, \( x_{-i} \). The function is represented by a mapping \( \phi^i : V \times V \rightarrow Z \subseteq \mathbb{R} \). The bias parameter \( b_i \) measures the conflict of interest between the two agents. This captures the extent to which the goals of the agents differ relative to the underlying state of the project.

The utility function \( U : V^2 \times \Theta \times \mathbb{R} \rightarrow \mathbb{R} \) is twice continuously differentiable, \( U_{11}(\cdot) < 0, U_{12}(\cdot) > 0, \) and \( U_{13}(\cdot) > 0 \) such that \( U \) has a unique maxima for any given pair \((\theta, b_i)\). For sake of exposition, let the bias of the uninformed agent be nor-

\[ \text{Partitional equilibria of the kind developed by Crawford-Sobel are also ruled out on the interval } (\frac{1}{5}, 1]. \] The incentive to exaggerate ensures that if there are two partitions, say, boundary types in the lower partition would find it profitable to deviate to the higher partition, precluding the existence of an indifference type. See Lemma 1 for more.
malized to $b_1 = 0$ and that of the informed to $b_2 = b > 0$.\footnote{Notice that including a conflict of interest is not necessary for the analysis and the main results. Instead one could vary the coordination functions to generate the same trade-offs.} Let $\bar{\phi}_1^\theta \equiv \arg\max_{\phi^1} U (\phi^1, \theta)$ and $\bar{\phi}_2^\theta \equiv \arg\max_{\phi^2} U (\phi^2, \theta, b)$ be the first best levels of joint actions for the two agents respectively, for a given $\theta$. The above setup induces a Bayesian game with one sided incomplete information given by $\Gamma = (\mathcal{I}, \mathcal{V}, \Theta, F, \{\phi^i\}_{i \in \mathcal{I}})$.

The coordination function $\phi^i(\cdot)$ is increasing, twice continuously differentiable and concave in the actions of both agents, $x_1$ and $x_2$. I make the following further assumptions on the functional form of the coordination function $\phi^i(\cdot)$:

**Assumption 1.** Increasing marginal contribution: $0 < \frac{\partial \phi^i(\cdot)}{\partial x_i} = \frac{\partial \phi^j(\cdot)}{\partial x_j} < \infty$

**Assumption 2.** Positive spillover: $0 < \frac{\partial \phi^i(\cdot)}{\partial x_j} = \frac{\partial \phi^j(\cdot)}{\partial x_i} < \infty$

**Assumption 3.** Imperfect substitutability: $\left(\frac{\partial \phi^i}{\partial x_i}\right) \left(\frac{\partial \phi^i}{\partial x_j}\right) > 1$

Assumption 1 ensures that the function is strictly increasing and bounded in each agent’s own action, while the second assumption ensures the same with respect to the other agent’s action. Assumption 3 implies that the marginal contribution effect dominates the spillover effect. The assumptions guarantee that the utility function satisfies the condition $\frac{\partial^2 U}{\partial x_i \partial x_j} < 0$, implying that actions of the two agents are substitutable.\footnote{To see this consider the derivative $\frac{dU}{dx_i} = \frac{\partial U}{\partial \phi^i} \frac{\partial \phi^i}{\partial x_i}$. Differentiating this expression with respect to $x_{-i}$ gives $\frac{\partial^2 U}{\partial x_i \partial x_j} = \frac{\partial^2 U}{\partial \phi^i \partial \phi^j} \frac{\partial \phi^i}{\partial x_i} \frac{\partial \phi^j}{\partial x_j} < 0$ since the coordination function is additively separable in $(x_1, x_2)$.} Further, the payoffs exhibit a shared costs feature, instead of the free riding (marginal costs) property that is commonly observed in games with action substitutability (e.g., Dubey et al., 2006). That is there is a cost associated with the positive externality generated from each agent’s action on the other agent’s coordination function. As a result, each agent’s cost is determined by the total value of their respective coordination function, and not only by individual actions. In alliances, for example, this could be a reputational cost incurred for partnering in a military operation with another country, or nation-building costs that are incurred jointly when countries work together for post-conflict rehabilitation efforts.
Finally, I make the following assumption that considers a class of games with an 
generalized aggregative property (Acemoglu and Jensen, 2013; Jensen, 2010).

**Assumption 4.** **Aggregator function:** There exists a continuous and additively separable aggre-
gator \( \psi : V \times V \rightarrow S \subset \mathbb{R} \) and a transformation \( \phi^i : V \times S \rightarrow Z \) such that,

\[
\phi^i(x_i, x_{-i}) = \tilde{\phi}^i(x_i, \psi(x))
\]

The additive separability of \( \psi(x) \) implies there exists strictly increasing functions \( H, h_1, h_2 : \mathbb{R} \rightarrow \mathbb{R} \) such that \( \psi(x) = H(h_1(x_1) + h_2(x_2)) \) (see, e.g., Gorman, 1968).\(^{13}\)

Given a generalized aggregator function, the underlying game can be represented as a 
Bayesian Aggregative Game.

**Definition 1.** Let \( \tilde{\Gamma} = (\mathcal{I}, V, \Theta, F, \{\tilde{\phi}^i\}_{i \in \mathcal{I}}) \) represent a Bayesian Aggregative Game such that,

\[
U\left(\phi^i(x_1, x_2), \theta\right) = U\left(\tilde{\phi}^1(x_1, \psi(x)), \theta\right)
\]

\[
U\left(\phi^2(x_2, x_1), \theta, b\right) = U\left(\tilde{\phi}^2(x_2, \psi(x)), \theta, b\right)
\]

A pure strategy Bayesian Nash Equilibrium (henceforth BNE) of the game without 
communication can be defined as follows:

**Definition 2.** **(BNE)** A profile of actions \( \{x^B(\theta)\}_{\theta \in \Theta} \), where \( x^B(\theta) \equiv (x^B_1, x^B_2(\theta)) \) constitutes

a Nash equilibrium of the Bayesian Aggregative Game if,

\[
x^B_1 \equiv \arg \max_{x_1 \in V} \mathbb{E}_\theta \left[ U\left(\tilde{\phi}^1(x_1, \psi(x^B(\theta))), \theta\right) \right]
\]

\[\forall \theta \in \Theta : x^B_2(\theta) \equiv \arg \max_{x_2 \in V} U\left(\tilde{\phi}^2(x_2, \psi(x^B(\theta))), \theta, b\right)\]

\(^{13}\)In the example of Section 2 the aggregator is a linear function. That is \( h_i(x_i) = x_i, \psi(x) = \frac{\eta}{1 + \eta}(x_1 + x_2), \)

and \( \phi^i(x_i, \psi(x)) = \frac{1-\eta}{1+\eta}x_i + \frac{\eta}{1+\eta}(x_1 + x_2) \). Alternatively, \( \phi^i(x_i, x_j) = \frac{ax_i + \beta x_j}{a + \beta} \)

where \( a > \beta \) such that \( h_i(x_i) = x_i, \psi(x) = \frac{\beta}{\alpha + \beta}(x_1 + x_2), \) and \( \phi^i(x_i, \psi(x)) = \frac{a-\beta}{\alpha + \beta}x_i + \frac{\beta}{\alpha + \beta}(x_1 + x_2) \). In this case, the parameters are 
sufficient to induce conflicting interests.
If the Bayesian Aggregative Game admits an equilibrium and moreover an unique one in agents’ action for any given prior \( f \), then it follows that adding communication would also similarly result in uniqueness of equilibrium actions. Specifically, the posterior beliefs that strategic communication induces might differ according to the messaging equilibrium but existence and uniqueness of the best responses in the Bayesian game post-communication would continue to hold. With this in mind, the following theorem establishes the existence and uniqueness of BNE of a Bayesian Aggregative Game.

**Theorem 1.** There exists an unique BNE of the Bayesian Aggregative Game.

**Proof.** See Appendix A.1.

The main tool required for the above result is the notion of aggregate backward response correspondence.\(^\text{14}\) The equilibrium of the game is a fixed point of the aggregate backward response correspondence. To guarantee the existence of a fixed point, the underlying game has to be a nice aggregative game.\(^\text{15}\) Assumptions 1-4 ensures that the backward response correspondences are upper hemi-continuous and there exists a fixed point (Kakutani’s theorem) of the game. Clearly, in the presence of information asymmetry, only the informed agent is able to adjust actions according to her private information while the uninformed \( A_1 \) takes an expected action (possibly the boundary action \( x^B_1 = \inf V \)) such that the local maxima conditions are satisfied. The equilibrium actions of the agents in the game can be defined as a set consisting of a pair of actions \( x(\theta) = (x_1, x_2(\theta)) \) and an aggregate \( Q(\theta) = \psi((x(\theta))) \) for every \( \theta \in \Theta \). Since there is an unique value of the coordination function for every type, and the function itself is concave in the actions of the two agents, it follows from standard concavity arguments that the equilibrium actions are necessarily unique. Specifically, there is an unique pair of actions for every \( \theta \in \Theta \) such that \( \tilde{\phi}_i(x_i(\theta), \psi(x(\theta))) = \tilde{\phi}_\theta \) for \( i = \{1, 2\} \).

\(^{14}\)The detailed notations are confined to the Appendix.

\(^{15}\)See Definition 6 in Acemoglu and Jensen (2013).
4 Communication Equilibria

Given uniqueness of equilibrium in the action stage, I revert back to the original formulation of the model to characterize the set of communication equilibria prior to the action stage. Following Kartik (2009), let $M = \bigcup_{\theta} M_{\theta}$ be a Borel space of messages available to $A_2$ such that $\forall \theta, \theta' \in \Theta : M_{\theta} \cap M_{\theta'} = \emptyset$. The strategic communication game, or the "Simultaneous Protocol", proceeds in two stages.

- In the first stage, $A_2$ observes the true state $\theta \in \Theta$ and sends a message $m \in M$ to $A_1$. Let this messaging strategy be defined by a mapping $\mu : \Theta \rightarrow M$ and the message $m = \mu(\theta)$.

- In the second stage, both agents simultaneously take actions $\alpha_1 : M \rightarrow V$ and $\alpha_2 : \Theta \times M \rightarrow V$.

An equilibrium of the simultaneous protocol game is a Perfect Bayesian Equilibrium in monotone messaging (pure) strategies\footnote{In the analysis, I restrict attention to message monotonicity in that if $\theta' > \theta''$ then $\mu(\theta') \geq \mu(\theta'')$. Refer to Kartik (2009) for more on this.} that satisfies the following properties:

- $A_1$ and $A_2$ simultaneously choose actions $(x_1^*(m), x_2^*(\theta, m))$ that maximizes their expected utility according to the optimization problem:

$$x_1^*(m) \equiv \arg \max_{x_1 \in V} \mathbb{E}_{\theta|m} \left[ U\left( \phi^1(x_1, x_2^*(\theta, m)), \theta \right) \right] \text{ subject to } x_1 \in V$$ (1)

$$x_2^*(\theta, m) \equiv \arg \max_{x_2 \in V} \left[ U\left( \phi^2(x_2, x_1^*(m)), \theta, b \right) \right] \text{ subject to } x_2 \in V$$ (2)

- the coordination function maximizes each players' expected utility conditional on their information, ie, $\phi^1(x_1^*(m), x_2^*(\theta, m)) \equiv \arg \max_{\phi_1} U\left( \phi^1(x_1, x_2), \theta \right)$ and $\phi^2(x_2^*(\theta, m), x_1^*(m)) \equiv \arg \max_{\phi_2} U\left( \phi^2(x_2, x_1), \theta, b \right)$
• the posterior beliefs, given by a cdf $P(\theta \mid m)$, are updated using Bayes’ rule whenever possible, given the messaging rule $\mu^*(\theta)$

• given the beliefs and second stage actions $x_1(m)$ and $x_2(\theta, m)$, $A_2$ chooses a messaging strategy that maximizes expected payoff in the first stage,

$$
\mu^*(\theta) \in \arg \max_{m \in M} \int_{\theta \in \Theta} U \left( \phi^2(x_2(\theta, m), x_1(m)), \theta, b \right) dP(\theta \mid m)
$$

A PBE always exists in games with cheap talk. The babbling equilibrium in which the agent $A_2$’s message is ignored and $A_1$ takes an action based on the prior distribution of the state, is equivalent to the BNE of the aggregative game described in Theorem 1. Going forward, I try to identify conditions under which more informative communication equilibria emerge.

**Full Information Revelation**

When can the two agents share information efficiently? In other words, can all the private information held by $A_2$ be completely revealed to $A_1$, meaning $\mu(\theta) = \theta$ for all $\theta \in \Theta$. To see if a fully revealing equilibrium exists, it is important to understand the incentives of the informed agent $A_2$. For truthful messaging to be an equilibrium, $A_2$ must achieve first best for every possible state $\theta$. Since $A_2$ is constrained, the bounds on her action set given by $\inf V = \underline{k}$ and $\sup V = \bar{k}$ directly affects $A_2$’s ability to achieve first best. Therefore, the domain of available actions $V$ acts as an incentive compatibility constraint for truth-telling. Given this intuition, it is convenient to reformulate the second stage problem when $A_2$ has an unrestricted action domain to choose from.

**Definition 3. Unconstrained actions:** Let $\bar{x}_2(\theta, m)$ be the optimal action of $A_2$ when i) $x_2 \in \mathbb{R}$; and ii) message $m$ is believed by $A_1$ to be the true state.
\[ \bar{x}_2(\theta, m) \text{ solves } \max_{x_2 \in \mathbb{R}} U \left( \phi^2(x_2, \bar{x}_1(m)), \theta, b \right) \text{ subject to } \]
\[ \bar{x}_1(m) \equiv \arg \max_{x_1 \in V} U \left( \phi^1(x_1, \bar{x}_2(\theta, m)), m \right) \]

Further, when communication is truthful (\( m = \theta \)), let the optimal action of players under the unconstrained problem be \( \bar{x}_1(\theta) \) and \( \bar{x}_2(\theta) = \bar{x}_2(\theta, \theta) \).

**Assumption 5.** \( \bar{k} \leq \bar{x}_2(0) \leq \bar{k} \)

**Definition 4.** Highest type incentive compatibility (**HTIC**)\(^{17} \): \( \bar{x}_2(1) \leq \bar{k} \)

**Definition 3** does not necessarily prescribe the action of \( A_2 \) in equilibrium. Instead, \( \bar{x}_2(\theta, m) \) allows us to intuitively characterize the response of an informed agent when the message misrepresents the true state but is believed to be true by a naive \( A_1 \). **Assumption 5** ensures trivial equilibria are ruled out (i.e., where no information is revealed credibly). Finally, **Definition 4** provides a necessary and sufficient condition for monotone separating (full revelation) equilibrium. **HTIC** implies that the best response of \( A_2 \) after truthfully communicating the highest state \( \theta = \sup \Theta \) is within the domain of feasible actions. This enables the informed agent to achieve first best levels of the coordination function \( \bar{\phi}_\theta \) under a perfectly revealing messaging strategy.\(^{18} \)

**Theorem 2.** A fully separating equilibrium exists if and only if **HTIC** condition is satisfied.

**Proof.** See Appendix A.2  

The underlying intuition of **Theorem 2** is straightforward. When **HTIC** is satisfied, it also implies that \( \bar{x}_2(\theta) \leq \bar{k} \) for every \( \theta \in \Theta \). The **HTIC** condition therefore ensures that the action constraints are never binding for \( A_2 \) under truthful revelation. This implies the informed agent can reveal her information and achieve full efficiency. On the other hand

\(^{17}**HTIC** is not related to the *No incentive to separate* (NITS) condition proposed by Chen, Kartik, and Sobel (2008).

\(^{18}**Throughout the paper, I will refer to miscoordination of the form \( \phi^i(.) > \bar{\phi}_\theta^i \) as *over-provision* and \( \phi^i(.) < \bar{\phi}_\theta^i \) as *under-provision*. **
if HTIC is violated but full separation exists, then there exists types for whom the actions are constrained by $\bar{k}$. Therefore the coordination function is strictly lower than the first best (under-provision) under truthful messaging for these types. This provides incentives for such types to jump to a higher message and pretend to be a higher type so that the uninformed agent $A_1$ takes a higher action to compensate for the mis-coordination losses. This incentive to exaggerate breaks down the full separation strategy.

**Partial Information Revelation**

This section focuses on equilibria that emerge in the presence of binding constraints on the agents. The following assumption ensures an intuitive characterization of informative equilibria.

**Assumption 6.** $k \leq \bar{x}_2(0,1) \leq \bar{k}$

Assumption 6 is a stronger version of Assumption 5 and essentially ensures any exaggeration by $A_2$ feasible in that it would induce an action by $A_2$ that is within the permissible set of actions. The pertinent question that arises is when would the informed agent have an incentive to exaggerate her private information? This happens precisely when there exists states for which truthful communication can never be credible. Observe that when HTIC condition fails, then there must exist a cutoff $\bar{\theta}$ such that $\bar{x}_2(\bar{\theta}) = \bar{k}$. Let $G = \{\theta : \bar{x}_2(\theta) > \bar{k}\}$ be the set of states for which truthful revelation results in the constraint being binding on $A_2$. The cutoff state $\bar{\theta} = \sup\{\Theta \setminus G\}$ therefore provides an upper bound on the extent of truthful communication. None of the messages beyond $\bar{\theta}$ are credible in any equilibria of the communication game.\(^{19}\)

---

\(^{19}\)This resembles the credibility notion of self-signaling, identified by Aumann (1990), and Farrell and Rabin (1996). When the unconstrained action is above the bound, it implies that the action constraints are binding, and the equilibrium actions is $\bar{x}_2^*(\theta) = \bar{k}$. Given imperfect substitutability, the informed agent’s action has a positive spillover implying that $U_1(\phi^2(\bar{k}, \bar{x}_1(\theta)), \theta, b) > 0$. This ‘positive spillover effect’ implies that communication ceases to be credible, since $A_2$ (strictly) prefers to induce a higher action from $A_1$, by inflating her private information. See Baliga and Morris (2002) for more on this point.
Lemma 1. When HTIC is violated, all types in set $G$ pool on the same message in every equilibrium of the communication game.

Proof. See Appendix A.3 □

The intuition behind Lemma 1 is the following. Suppose it was possible for $A_2$ to partition the set $G$ into two - $G_1 = ([\bar{\theta}, \bar{\theta}_g]$ and $G_2 = ([\bar{\theta}_g, \bar{\theta}]$. Then, there are always types that are pooled in the first partition for whom $A_2$’s optimal action is constrained by the bound $\bar{k}$. This implies that for some types in $G_1$, $A_2$ would have an incentive to exaggerate and pool with the higher types in $G_2$, precluding the possibility of such a partition in equilibrium. Therefore, in the presence of constraints, two things hold: $i)$ at most, there is only partial revelation of information; and $ii)$ no credible information is conveyed beyond $\bar{\theta}$. The next theorem characterizes the set of all partially revealing threshold equilibria.

Theorem 3. When HTIC is violated, there are Partially Revealing Threshold Equilibria (PRTE) such that, $\forall \theta^* \in [0, \bar{\theta}]$: $m(\theta) \in M_0$ if $\theta \in [0, \theta^*]$ and $m(\theta) = \bar{m} \in \bigcup_{t \in [\theta^*, \bar{\theta}]} M_t$ if $\theta \in (\theta^*, \bar{\theta}]$.

The actions of agents are the following:

- $\forall m(\theta) \in \bigcup_{\theta \in [0, \theta^*]} M_0 : x_1^*(m(\theta)) = \bar{x}_1(\theta), x_2^*(\theta, m(\theta)) = \bar{x}_2(\theta)$

- If $m(\theta) = \bar{m}$,

  \[-x_1^*(\bar{m}) \equiv \arg \max_{x_1 \in V} \int_{\theta \in [\theta^*, \bar{\theta}]} U(\phi_1(x_1, x_2^*(\theta, \bar{m})), \theta) \, dP(\theta|\bar{m})\]

  \[-x_2^*(\theta, \bar{m}) \equiv \arg \max_{x_2 \in V} U(\phi_2(x_2, x_1^*(\bar{m})), \theta, \bar{b})\]

Proof. See Appendix A.4 □

Two things stand out from Theorem 3. First, there is complete pooling above a certain cutoff state, while every message within the cutoff is truthful. Second, there

\[20\]On a similar vein, Ottaviani and Squintani (2006) construct a cutoff equilibrium in which messages are revealing (albeit inflated) below the threshold, and for states above the cutoff, information transmission is partitional in nature. See also Kartik (2009) and Kartik et al. (2007).
is multiplicity of equilibria. $A_2$ could possibly choose how much information to reveal in equilibrium. In fact, the informed agent could choose to partition the information within the interval $[0, \bar{\theta})$, instead of revealing them truthfully. This is so because, under any PRTE, the constraints are satisfied with slack for any type in this interval. As a result, there is always a possibility to pool any type $\theta \in [0, \bar{\theta})$ with lower types within the interval such that the incentive compatibility conditions are satisfied. This gives rise to possibly multiple partitions.\textsuperscript{21} The following proposition characterizes all such monotone hybrid equilibria.

**Proposition 1.** Monotone Hybrid Equilibria (MHE): Fix a PRTE with threshold $\theta^* < \bar{\theta}$. For every such $\theta^*$ equilibrium, there exists $i \in \{1, 2, ..., N\}$ and,

- Types $\langle t_0 = \theta, t_1 = \theta_1, ..., t_N = \theta^* \rangle$, actions $\langle k_1, k_2, ..., k_N \rangle$, and messages $m_i = (t_{i-1}, t_i)$,

\[
m_{N+1} = (\theta^*, \bar{\theta})\text{ such that } \forall i \in \{1, 2, ..., N\},
\]

\[
- x_1^*(m_i) = \arg\max_{x_1 \in V} \int U(\phi_1(x_1, x_2^*(\theta, m_i)), \theta) \, dP(\theta | m_i)
\]

\[
- x_2^*(\theta, m_i) = \arg\max_{x_2 \in V} U(\phi_2(x_2, x_1^*(m_i)), \theta, b) \text{ and } x_2^*(t_i, m_i) = k_i
\]

\[
- \forall \theta \in m_i : \phi_2(x_2^*(\theta, m_i), x_1^*(m_i)) = \bar{\phi}_{\theta}
\]

- For the pooling message $m_{N+1} = (\theta^*, \bar{\theta})$,

\[
- x_1^*(m_{N+1}) \equiv \arg\max_{x_1 \in V} \int U(\phi_1(x_1, x_2^*(\theta, m_{N+1})), \theta) \, dP(\theta | m_{N+1})
\]

\[
- x_2^*(\theta, m_{N+1}) \equiv \arg\max_{x_2 \in V} U(\phi_2(x_2, x_1^*(m_{N+1})), \theta, b)
\]

**Proof.** Appendix A.5 \hfill \Box

In the hybrid equilibria, the informed agent chooses multiple message pools up to a certain threshold and pools all the information above this threshold. The novel feature of these equilibria is that they are different in structure to the classical partitional equilibria \textsuperscript{21} Notice however that in all such equilibria, the types belonging to $G = (\bar{\theta}, \bar{\theta}]$ are always pooled together.
in that they are not monotonically increasing in size. The size of the message pools instead depends on the equilibrium action of the marginal type in the interval, i.e., the indifference condition is pinned down by the action of the boundary type for any two adjacent messages. Incentive compatibility dictates that the boundary type’s actions corresponding to the two messages must not be binding, meaning that the informed agent is able to achieve first best levels of coordination function for either of the two adjacent messages.

**Efficiency**

As is the case with cheap talk models, there is a multiplicity of equilibria in this setup. An important question that arises is the relationship between information transmission and welfare of agents. To analyze this, it is important to study the response of agents when the information is pooled. Since both players take actions, the informed agent $A_2$ now has an additional instrument via her action. This ability to take an action after the communication stage allows $A_2$ to undo some of the inefficiencies from pooling information. The best-response of $A_1$ similarly entails an important trade off. $A_1$ chooses an action such that $A_2$ is unable to achieve first best levels of coordination for some types within the interval, i.e. there exists a measure of types such that for all types in that interval, $\theta_2 = \bar{k}$. Figure 2 illustrates this point ($\Theta \equiv [0, 1]$). Notice that there is non-monotonicity in $A_2$’s action at $\theta^*$ because of the discontinuous jump in $A_1$’s response upon receiving the pooling message. Since $A_1$’s action has a discontinuity at $\theta^*$, the informed agent is able to readjust her actions to achieve first best. Further, since $A_1$’s action is not high enough, there is always an interval of types $[\theta^*, \tilde{\theta}]$ for which the constraint is binding for $A_2$.

**Proposition 2.** The most informative equilibrium, $\theta^* = \tilde{\theta}$, is ex ante efficient for both agents.

*Proof. See Appendix A.6*
Both agents benefit from more information sharing. For $A_1$ a greater threshold of information implies first best on the separating interval and lesser variance on the pooling interval. These twin effects reinforce each other in the higher informational equilibrium. A greater threshold of information also implies that for $A_2$ the constraints on the action set are binding for a smaller measure of types. Further, a higher threshold corresponds with a higher action from $A_1$ on the pooling interval. Both these effects provide $A_2$ with a greater ex ante welfare under more informative equilibria. Figure 3 shows these tradeoffs. On the left, under a less informative threshold, $A_1$’s action is lower on the pooling interval and this directly affects the informed agent’s ability to achieve first best.

Notice that the equilibrium welfare under any $MHE$ with $\theta_N = \theta^*$ is strictly dominated by the corresponding $PRTE$ in which information is revealed fully up to $\theta^*$. This
is straightforward to observe. For the informed agent there is no difference in welfare between MHE and PRTE. For the uninformed agent, however, the PRTE is strictly better on the separating interval $[\bar{\theta}, \theta^*]$ since there is no variance losses associated with partial pooling on this interval.

**Corollary 1.** Given any MHE with $\theta_N = \theta^* < \bar{\theta}$, the corresponding PRTE with an information threshold $\theta^*$ is ex ante pareto dominant for both agents.

## 5 Optimal Commitment

In this section, I focus on the role of commitment in mitigating some of the inefficiencies arising from communication. Typically in alliances countries commit to international agreements (e.g., NATO Strategic Concept or EU PESCO agreement) that specifies the level of commitment and contribution to the alliance. To characterize this I study a one-sided commitment mechanism (or commitment rule) $(\mathcal{M}, T_1)$ under which the uninformed agent commits to a deterministic decision rule contingent on the message space, i.e. $T_1 : \mathcal{M} \to V$. The informed agent chooses a subsequent action strategically (no commitment)
by best responding to the commitment rule of $A_1$, i.e. $T_2 : \Theta \times V \rightarrow V$. In other words, the action of $A_1$ is contractible while that of $A_2$ is non-contractible.$^{22}$

Without loss of generality, I restrict attention to deterministic direct mechanisms $D = (\Theta, T_1)$ where $M = \Theta$ is the message space and the decision rule for $A_1$ is simply $T_1 : \Theta \rightarrow V$. Further, there are no contingent transfers allowed between the agents (Alonso and Matouschek, 2008; Melumad and Shibano, 1991). This is in line with observed practices in international alliances that disallow conditional transfers between countries, but instead allow for direct contributions to the alliance in order to achieve stated objectives. The optimal commitment rule problem for $A_1$ is given by the following:

$$\arg\max_{x_1^c(\theta) \in V} \int_{\Theta} U\left(\phi^1(x_1^c(\theta), x_2^c(\theta, x_1^c(\theta))), \theta\right) dF$$

subject to:

$$(NC) \quad x_2^c(\theta, x_1^c(\theta)) \equiv \arg\max_{x_2 \in V} U\left(\phi^2(x_2, x_1^c(\theta)), \theta, b\right)$$

$$(IC) \quad \forall \theta, \theta' \in \Theta : \quad U\left(\phi^2(x_2(\theta, x_1^c(\theta))), x_1^c(\theta), \theta, b\right) \geq U\left(\phi^2(x_2(\theta, x_1^c(\theta')), x_1^c(\theta')), \theta, b\right)$$

The optimal commitment rule for the uninformed agent resembles the classical constrained delegation problem studied by Holmstrom (1978) with a crucial difference. $A_1$ maximizes the ex ante expected utility subject to a non-contractibility (NC) constraint for the informed agent $A_2$, in addition to the standard incentive compatibility constraints.$^{23}$

$^{22}$This is in stark contrast to problems of imperfect commitment studied by Bester and Strausz (2001) and Krishna and Morgan (2008). In Bester and Strausz (2001) for example the uninformed principal makes two decisions, only one of which is contractible. In a similar vein Krishna and Morgan (2008) study imperfect contracting in which the principal is able to commit to contingent transfers but is free to choose the actions (project choice in their paper).

$^{23}$There are no participation constraints in the commitment problem. However, adding an ex ante constraint such that $\int_{\Theta} U\left(\phi^2(x_2(\theta, x_1^c(\theta))), x_1^c(\theta), \theta, b\right) dF \geq \bar{u}$ would not affect the solution to the commitment problem as long as the $\bar{u}$ is within reasonable thresholds. For example, if $\bar{u}$ is less than the expected payoff from the simultaneous protocol, then that would satisfy agent $A_2$’s participation constraint (see Proposition 6).
The main source of inefficiency under the simultaneous protocol was the miscoordination losses on the pooling interval for $A_1$. This was driven by the fact that $A_1$ took a single action in expectation while $A_2$ adjusted her actions in order to satisfy her first best, and in the process over-contributed (imperfect substitutability) leading to miscoordination. By instead committing to an ex ante action rule, $A_1$ can mitigate some of this inefficiency. The commitment protocol allows the uninformed agent to contribute a sequence of actions on $\Theta$ conditional on satisfying the IC and NC constraints.

Therefore, the solution to the commitment problem is akin to minimizing the miscoordination losses for the agent $A_1$. On the interval $[\tilde{\theta}, \bar{\theta}]$ this amounts to choosing exactly the same actions as in the simultaneous protocol, i.e. $\bar{x}_1(\theta)$. By doing so, the agent forces $A_2$ report truthfully and take a best responding action $\bar{x}_2(\theta)$ such that both agents achieve their first best levels of coordination functions $\bar{\phi}_i$. When it comes to the pooling interval, henceforth $\bar{m}_p \equiv (\tilde{\theta}, \bar{\theta})$, $A_1$’s problem becomes equivalent to finding a monotone increasing sequence of actions that minimizes expected miscoordination. The following lemma provides the fundamental intuition for $A_1$’s choice of actions on $\bar{m}_p$.

**Lemma 2.** If $x_1^c(\theta)$ is strictly increasing on any interval $(\theta_1, \theta_2)$ within $\bar{m}_p$, then $x_2^c(\theta, x_1^c(\theta)) = \bar{k}$ for all types in this interval.

*Proof.* See Appendix A.7. □

The intuition behind Lemma 2 is driven by two observations. First, in order to satisfy the NC (ipso facto, IC) constraint of $A_2$ any strictly increasing sequence of actions by $A_1$ on $\bar{m}_p$ must ensure first best levels of the coordination function to the informed agent ($\phi^2 = \bar{\phi}_\theta^2$).

Second, $A_1$’s choice of actions must be such that they also simultaneously reduce the extent of miscoordination. **Lemma 2** argues that while there are a number of different ways in which $A_2$’s IC can be satisfied, the one that minimizes $A_1$’s miscoordination loss is the one in which $A_2$ contributes $x_2^c = \bar{k}$. If this weren’t true, $A_1$ could

---

24 This is akin to the provision of *informational rents* in the classical mechanism design literature.
increase the expected payoff by decreasing her actions and inducing a higher action from $A_2$ on the separating interval.

Figure 4 illustrates these points clearly. Consider for example the action of $A_1$ on the pooling interval under the simultaneous protocol. Specifically, $A_1$ instead of taking an action $x_1^s(\bar{m}_p)$ on $(\bar{\theta}, \bar{\theta}_s)$, pivots down and commits to a sequence of actions such that $x_1^c(\theta) < x_1^s(\bar{m}_p)$. Further, this action is chosen in a way that $A_2$ best responds by playing $\bar{k}$ (see Figure 4(b)). $A_2$ achieves first best levels $\bar{\phi}_2^2$ while for $A_1$ the miscoordination is lesser compared to the simultaneous protocol.

The presence of the NC constraint overturns some of the regular results in the delegation literature.\(^{25}\) Specifically, given NC any rule that takes the same action over the entire pooling interval cannot be optimal for $A_1$ for two reasons. Firstly, $A_2$ will readjust actions accordingly to achieve her first best which implies over-provision and miscoordination for $A_1$. Secondly, this miscoordination is exacerbated by the fact that $x_2^c(.) < \bar{k}$ for some positive measure of types. By applying a similar reasoning, multiple pools or separating regions, or a separating region following a pooling decision interval can

\(^{25}\)See e.g. Ambrus and Egorov (2017), Alonso and Matouschek (2008) and Melumad and Shibano (1991). In these papers typically the decision rule involves multiple pooling intervals followed by or interspersed with separating regions.
also be ruled out. The following claims establish these key results (the broad intuition is
detailed below and the formal proofs are confined to the appendix).

**Claim 1.** On the interval $\bar{m}_p$ there is no single flat segment such that $\forall \theta \in \bar{m}_p : x^c_1(\theta) = z \geq \bar{x}_1(\bar{\theta})$.

**Claim 2.** On the interval $\bar{m}_p$ there cannot exist more than one pooling (flat) segments. That is, $I = \{z_i : \exists \theta_i, \theta'_i \in \bar{m}_p \text{ and } \forall \theta \in (\theta_i, \theta'_i) \text{ s.t } x^c_1(\theta) = z_i \} \text{ and } z_j \neq z_l$ such that $|I| > 1$ cannot be optimal for $A_1$.

Suppose $x^c_1(\theta) = \bar{x}_1(\bar{\theta})$. Then $\forall \theta \in \bar{m}_p : x_2(\theta) = \bar{k}$. This cannot be optimal since $A_1$ can always do better by committing a bit more and satisfying $A_2$’s NC/IC constraints. Instead, suppose $x^c_1(\theta) = z > \bar{x}_1(\bar{\theta})$. Say, for the sake of argument that $z = x^*_{i}$, i.e. $A_1$ mimics the action under simultaneous protocol. This again cannot be optimal since agent $A_2$’s action is less than $\bar{k}$ on the interval $(\bar{\theta}, \bar{\theta}_s)$. $A_1$ can instead always commit to lesser and induce $A_2$ to contribute $\bar{k}$. Given the findings from Lemma 2 this increases the expected payoff to agent $A_1$ by minimizing miscoordination on $\bar{m}_p$. For similar reasons, multiple decision pools are infeasible due to the NC constraint. If suppose, for sake of argument there were two different pools with actions $z_1$ and $z_2$ respectively (wlog $z_1 < z_2$). Then either the agent on the $z_1$ pooling region achieves first best or she deviates to the higher pooling region. In the former case it implies $x^c_2 < \bar{k}$ which is inefficient for the same reasons as argued earlier. In the latter case, jumping to the higher pool violates IC and the decision rule cannot be efficient for $A_1$ as a result.

**Claim 3.** On $\bar{m}_p$, there cannot be a flat segment followed by a strictly increasing interval.

**Claim 4.** There cannot be discontinuous strictly increasing separating intervals on $\bar{m}_p$.

**Claim 5.** There cannot be a fully separating decision rule on $\bar{m}_p$, i.e., $\forall \theta', \theta'' \in \bar{m}_p : x^c_1(\theta') \neq x^c_1(\theta'')$. 

28
Claim 3 follows from noting that on a flat segment either $A_2$’s IC is satisfied for all types in that interval or there is inefficiency for some types. If it is the former, then $A_1$ can improve its payoff (see Claim 1-2) and extracting $\bar{k}$ from $A_2$. If it is the latter, on the other hand, there exists types that do not achieve first best on the pooling region which means they can always deviate to the (strictly increasing) separating interval and benefit from higher actions of $A_1$, thereby violating IC constraint for truth-telling. Multiple separating segments are also inefficient because they create a discontinuous jump in the actions of $A_1$. This implies at the point where there is a jump, the informed agent’s action falls below $\bar{k}$. This cannot be an optimal decision rule (see Lemma 2). Finally, Claim 5 rules out fully aligned contracts that provide first best to $A_2$ on $\bar{m}_p$. Clearly this would entail over-provision for $A_1$ which implies $U_1 < 0$ on the whole interval.\footnote{This is similar to arguments in Krishna and Morgan (2008) that rule out fully aligned contracts that are optimal to the agent for all types of her private information. See Corollary 1 for more.}

The consequence of Claim 1-Claim 5 is that the optimal commitment rule for agent $A_1$ has an intuitively simple structure on the interval $\bar{m}_p$. It involves only a single separating interval up to a threshold $\bar{\theta}_c$ followed by a pooling action $x_1^c(\bar{\theta}_c)$ on the rest of the interval, as in Figure 5. Therefore the commitment rule problem reduces to choosing this optimal cutoff $\bar{\theta}_c$ given the NC and IC constraints. The following proposition provides the necessary characterization.

**Proposition 3.** The optimal commitment mechanism for $A_1$ is given by the following:

1. $\forall \theta \in [\bar{\theta}, \bar{\theta}_c] : x_1^c(\theta) = \bar{x}_1(\theta)$

2. $\exists \bar{\theta}_c \in \bar{m}_p$ that solves,

$$\begin{align*}
\bar{\theta}_c &\equiv \arg\max_{t \in \bar{m}_p} \int_{\bar{\theta}}^t U\left(\phi^1(x_1^c(\theta), \bar{k}), \theta\right) dF + \int_{t}^{\bar{\theta}} U\left(\phi^1(x_1^c(t), \bar{k}), \theta\right) dF \\
&\text{such that } \forall \theta \in (\bar{\theta}, \bar{\theta}_c] : x_1^c(\theta) \equiv \arg\max_{x_1 \in V} U\left(\phi^2(\bar{k}, x_1), \theta, b\right), \phi^2(\bar{k}, x_1^c(\bar{\theta}_c)) = \bar{\phi}_{\bar{\theta}_c}^2
\end{align*}$$
Figure 5: Under the ex ante commitment, $A_1$ can pivot down on $\bar{m}_p$ (see 5(a) and 5(c)). This induces $\bar{k}$ from $A_2$ (see 5(b) and 5(d)) under commitment.

3. $\forall \theta \in (\bar{\theta}_c, \bar{\theta}): x_i^c(\theta) = x_i^c(\bar{\theta}_c)$

Proof. See Appendix A.8

The optimal decision rule $i$ mimics the simultaneous protocol on $[\theta, \bar{\theta}]$; $ii$ is strictly separating in the region $(\bar{\theta}, \bar{\theta}_c]$ such that $A_2$ always takes the highest action available, $\bar{k}$; and $iii$ is invariant (pooling action) for the rest of the types. Two important properties of the optimal commitment rule becomes clear from Proposition 3. First, the commitment rule neutralizes the NC constraint by extracting the maximal action from $A_2$ on the interval $\bar{m}_p$. Second, the rule entails capping of actions beyond the threshold $\bar{\theta}_c$. As a result the optimal rule is discontinuous at exactly $\bar{\theta}$ and nowhere else. By keeping the informed agent’s action pegged at $\bar{k}$, $A_1$ minimizes the informational inefficiencies that
were present with simultaneous decision-making.

**Proposition 4.** The optimal commitment rule improves ex ante welfare of both agents compared to the simultaneous protocol.

**Proof.** See Appendix A.9

The interesting conclusion of Proposition 4 is that both agents benefit from commitment. While it is well understood that commitment usually improves the uninformed player’s welfare (Glazer and Rubinstein, 2008), a number of papers on delegation find that the welfare effects of delegation is ambiguous and depends crucially on the extent to which the players’ interests are aligned (see, e.g., Alonso and Matouschek, 2008; Dessein, 2002). Proposition 4 suggests that irrespective of the alignment of interests and the size of the action set available, commitment is always pareto improving.

The rationale for this result can be gleaned by noting that the threshold $\bar{\theta}_s < \bar{\theta}_c$. The intuition for this is the following. Since $A_1$ induces $A_2$ to take the maximal action $\bar{k}$ on the interval $\bar{m}_p$ (Figure 5(d)), the marginal utility for $A_1$ is strictly increasing at $\bar{\theta}_s$ under commitment. This directly translates into higher welfare for $A_1$ under commitment. For $A_2$ the above means the cap on actions with commitment is also higher compared to the simultaneous protocol. That is $A_2$ achieves first best up to $\bar{\theta}_c$ and on the remaining interval of types, the miscoordination from under-provision is lower under commitment compared to the simultaneous protocol.

6 Uniform-Quadratic Example

Reconsider the example examined in Section 2. As in the example let the utility functions of the two agents be a quadratic loss function of the following form,

$$U^1 = - \left( \frac{x_1 + \eta x_2}{1 + \eta} - \theta \right)^2$$
$U^2 = -\left[ \left( \frac{x_2 + \eta x_1}{1 + \eta} \right) - \theta - b \right]^2$

In accordance with the analysis of the previous sections let $\phi^1(x_1, x_2) = \left( \frac{x_1 + \eta x_2}{1 + \eta} \right)$ and $\phi^2(x_2, x_1) = \left( \frac{x_2 + \eta x_1}{1 + \eta} \right)$ be the respective joint coordination functions of the two agents. The parameter $\eta \in (0, 1)$ measures the extent of interdependence between the two agents' actions. Let the action set of the two players be $V = [0, \tilde{k}]$, where the lower bound is normalized, $\tilde{k} = 0^{27}$. As in Section 2, the state is uniformly distributed ($\theta \in U[0, 1]$) and perfectly observed only by $A_2$. Finally, miscoordination is simply interpreted as $\phi^1(x_1, x_2) >> \theta$ for $A_1$, and $\phi^2(x_2, x_1) >> (\theta + b)$ for $A_2$. The informed agent is able to convey information as long as revealing the type does not result in miscoordination in the action stage. Specifically, it is straightforward to observe that when the state is known then,

$$x^*_1(\theta) = \theta - \frac{\eta}{1 - \eta} b; \quad x^*_2(\theta) = \theta + \frac{1}{1 - \eta} b \quad (3)$$

The most informative equilibrium $\tilde{\theta}$ with communication (simultaneous protocol) can

---

27This is without loss of generality since the lower bound does not affect the incentives of the informed player in the model.
be immediately calculated by solving the equations,

\[ x_1(\bar{\theta}) = (1 + \eta)\bar{\theta} - \eta \bar{k} \]

\[ \bar{k} = (1 + \eta)(\bar{\theta} + b) - \eta x_1(\bar{\theta}) \]

All the subsequent results are represented as functions of the exogenous variables \((\eta, b, \bar{k})\). This way, the analysis of the uniform quadratic setting leads to interesting comparative statics with respect to these parameters. The following proposition characterizes all the cutoffs under both simultaneous and commitment protocols.

**Proposition 5.** In the uniform quadratic setting,

(a) There is no fully revealing equilibria if \(\bar{k} \in \left((1 + \eta)b, 1 + \frac{1}{1-\eta}b\right)\); only PRTE exists.

(b) The most informative threshold is given by \(\bar{\theta} = \bar{k} - \frac{1}{1-\eta}b\) and \(\bar{m}_p = (\bar{\theta}, 1]\). The actions of the two agents for all \(\theta \in [0, \bar{\theta}]\) is given by \(x_1^s(\theta) = x_1^c(\theta) = \theta - \frac{\eta}{1-\eta}b\) and \(x_2^s(\theta) = x_2^c(\theta, x_1^c(\theta)) = \theta + \frac{1}{1-\eta}b\).

(c) On the interval \(\bar{m}_p\) without commitment (simultaneous protocol):

\[ \bar{\theta}_s = \frac{(4 + \eta)(1 - \eta)}{(4 + \eta)(1 - \eta) + \eta} \bar{k} - \frac{(4 + \eta)}{(4 + \eta)(1 - \eta) + \eta} b + \frac{\eta}{(4 + \eta)(1 - \eta) + \eta} \]

\[ x_1^s(\bar{m}_p) = \frac{((4 + \eta)(1 - \eta) - 1)}{(4 + \eta)(1 - \eta) + \eta} \bar{k} - \frac{(3 + \eta)(1 + \eta)}{(4 + \eta)(1 - \eta) + \eta} b + \frac{(1 + \eta)}{(4 + \eta)(1 - \eta) + \eta} \]

\[ x_2^s(\theta, \bar{m}_p) = \min \{ \bar{k}, \bar{k} - (1 + \eta)(\bar{\theta}_s - \bar{\theta}) \} \]

(d) On the interval \(\bar{m}_p\) under commitment protocol:

\[ \bar{\theta}_c = \frac{2(1 - \eta)}{(2 - \eta)} \bar{k} - \frac{2}{(2 - \eta)} b + \frac{\eta}{(2 - \eta)} \]

\[ \forall \theta \in (\bar{\theta}, \bar{\theta}_c): \quad x_1^c(\theta) = \frac{1 + \frac{\eta}{\theta + b} - \frac{1}{\bar{k}}} {\eta} \]
∀\(\theta \in [\bar{\theta}_c, 1] : x_1^c(\theta) = \frac{1 + \eta}{\eta}(\bar{\theta}_c + b) - \frac{1}{\eta}\bar{k}\)

∀\(\theta \in \bar{m}_p : x_2^c(\theta) = \bar{k}\)

(e) Let \(\bar{\theta}_d = \bar{\theta}_c - \bar{\theta}_s\). If \(\bar{k} \in (1 + \eta)b, 1 + \frac{1}{1-\eta}b\), then \(\bar{\theta}_d > 0\).

Proof. See Appendix B.1

The Proposition provides an intuitive closed form characterization of the most informative equilibria. Parts (a) and (b) result from the fact that if the truth-telling condition holds for the lowest type but not for the highest type then a cutoff in between must exist up to which there is full revelation and beyond which there is full pooling. In other words, the result identifies the precise conditions under which Assumption 5 holds and HTIC breaks down. The informational thresholds \(\bar{\theta}_s\) and \(\bar{\theta}_c\) represent the cutoffs up to which the informed agent achieves first best levels of coordination in the no commitment and commitment cases respectively. The expressions for the two thresholds follow from equation 8 and Proposition 3 respectively. The final part of the Proposition implies that in the case where only a PRTE exists, i.e. the conditions on \((\bar{k}, b, \eta)\) are according to part (a), the relation \(\bar{\theta}_c > \bar{\theta}_s\) always holds.

**Proposition 6.** In the uniform quadratic setting, the ex ante expected welfare of the agents are,

(a) Under simultaneous protocol:

\[
W_s^1 = -\frac{2}{3} \frac{(\eta^2 + 4\eta + 5)(1 - \eta)^2}{(4 - 2\eta - \eta^2)^2} \left(1 - \bar{k} + \frac{b}{(1-\eta)}\right)^2
\]

\[
W_s^2 = -\frac{1}{3} \frac{(4 + \eta)^2(1 - \eta)^2}{(4 - 2\eta - \eta^2)^2} \left(1 - \bar{k} + \frac{b}{(1-\eta)}\right)^2
\]

(b) Under commitment protocol:

\[
W_c^1 = -\frac{2}{3} \frac{(1 - \eta)^2}{(2 - \eta)^2} \left(1 - \bar{k} + \frac{b}{(1-\eta)}\right)^2
\]

34
\[ W_c^2 = -\frac{4}{3} \frac{(1 - \eta)^2}{(2 - \eta)^2} \left( 1 - \bar{k} + \frac{b}{(1 - \eta)} \right)^2 \]

(c) The welfare of both agents is increasing in \( \bar{k} \) and decreasing in \( b \), under both protocols.

(d) The welfare gains from commitment is positive for both agents, decreasing in \( \bar{k} \), and increasing in \( b \).

Proof. See Appendix B.2

The above Proposition provides some interesting insights. Firstly, it shows that the welfare of the agents – with or without commitment – is positively correlated with the information threshold \( \bar{\theta} = \left( \bar{k} - \frac{b}{(1 - \eta)} \right) \). That is, greater the information transmission threshold \( \bar{\theta} \), higher the welfare of agents. Secondly, as a direct consequence of the first point, any change in the exogenous parameters \( (\bar{k}, b) \) also affects the welfare of the agents by shifting the information threshold higher or lower. Finally, the value of commitment is always positive as long as there is no full revelation of information. However, the gains from commitment diminish as \( \bar{\theta} \) increases. The logic is intuitive. If more information is conveyed without commitment, then the measure of types on which there is miscoordination is smaller. Since the commitment protocol minimizes the miscoordination losses only on a narrower set of types, the value of commitment decreases. Clearly, an increase in \( \bar{k} \) or a decrease in the conflicts of interest \( b \) increases information threshold \( \bar{\theta} \) and as a result increases the welfare of agents but reduces the value of commitment.

7 An Application to International Alliances: Discussion

The theoretical results derived so far capture the trade-offs involved when there is a need for coordination between multiple decision makers, and decisions are substitutable. Often, this is the case when countries within an alliance work together to achieve common objectives. The theory presented in the paper offers some important insights for decision making in alliances.
Why contribute to alliances? Implications for information sharing and efficiency

One of the main insights of the analysis is that the action set available to the agents directly affects information revelation and thereby efficiency of outcomes. The intuition is straightforward. A greater upper bound increases the truthful communication threshold of the informed agent *information effect* and this increases efficiency for both agents (Proposition 2). For the uninformed agent too a greater upper bound is critical. For example if the optimal expected action is above the available set of actions, then the informed agent’s actions are constrained when information is pooled. The inability to take the optimum action implies inefficiency at the bound (expected utility is increasing at \( \bar{k} \)). As a result of this inefficiency, the informed agent too suffers as a lower action implies miscoordination (under-provision) for a greater measure of types. This increases miscoordination losses for both the informed agent and the uninformed agent (part (c) of Proposition 6).

In the context of alliances, the need for contributing resources cannot be understated. For example, US Presidents have long advocated for greater partnership and contributions from EU countries. Bush in 2006, Obama in 2014, and more recently Trump in 2018 have all pushed for a greater share of resource contributions from NATO’s European allies. See [https://www.cnbc.com/2018/07/11/obama-and-bush-also-pressed-nato-allies-to-spend-more-on-defense.html](https://www.cnbc.com/2018/07/11/obama-and-bush-also-pressed-nato-allies-to-spend-more-on-defense.html) for more on this point. Petersson (2015) writes, quoting from Obama’s “West Point speech” on May 28, 2014, “We cant have a situation in which the United States is consistently spending over 3 percent of our GDP on defense,” and Europe is spending 1 percent. “The gap becomes too large,” he continued, and the alliance needed to make sure that everybody was doing their fair share.”

---

29 Petersson (2015) writes, quoting from Obama’s “West Point speech” on May 28, 2014, “We cant have a situation in which the United States is consistently spending over 3 percent of our GDP on defense,” and Europe is spending 1 percent. “The gap becomes too large,” he continued, and the alliance needed to make sure that everybody was doing their fair share.”
informational and coordination rationale for more contributions. Having *skin in the game* is pareto improving for two reasons. First, it improves information revelation between members. Second, it reduces miscoordination that arises due to lack of sufficient resources.

**Why commitment in alliances? Implications for binding agreements**

The optimal commitment mechanism characterized in Proposition 3 has profound normative and positive implications. Specifically, the mechanism provides a framework for how binding agreements could be negotiated between parties seeking to work together in an alliance. The two main features of the optimal mechanism are i) maximal action by informed agent beyond a threshold of information, and ii) capping of actions by the uninformed agent. The latter is indirectly observed through commitment clauses proscribed in alliance agreements that specify *rules of thumb* for members’ defense spending (e.g. 2 percent of GDP in NATO or 2.5-3 percent of GDP under PESCO). Such *rules of thumb* clauses place an implicit commitment on countries to contribute without free riding on others and at the same time also provide an upper bound (cap) on the levels of spending they are obligated to undertake. All countries barring the US contribute lesser or equal to the proscribed amount in the case of NATO, for example.\(^{30}\)

The first feature (*maximal actions*), on the other hand, makes a normative point on the structure of ex ante agreements. One possible way to interpret the maximal action clause is the requirement for the more biased member to always contribute the highest possible resources when the information becomes more critical. The optimal mechanism, according to Proposition 3, must be such that the more biased member always contribute its full capacity to the operation in order to minimize miscoordination. In the war on terror over the last two decades, for example, the US regularly collected intelligence information about potential threats and possible opportunities to attack terrorist targets.\(^{30}\)

\(^{30}\)See Wittmann (2009) for an extensive analysis of NATO's Strategic Concept agreement.
Since the US is more biased, an agreement where the US contributes all its resources while the other members contribute only the residual resources required is the optimal one from an ex ante perspective.

The role of commitment in minimizing miscoordination is another central result of the paper. Proposition 4 argues that there are welfare gains for the informed agent from commitment. This is important since it provides a rationale for participating in such commitment contracts ex ante. Specifically, if the ex ante reservation utility (outside options) for the informed agent without commitment is the expected payoff from the simultaneous protocol, then the informed agent would always prefer the commitment protocol.\textsuperscript{31} The commitment protocol therefore provides an utilitarian rationale for binding agreements.

The welfare gains from commitment can be attributed to the reduction in miscoordination – from under-provision for the informed agent and over-provision for the uninformed – from commitment. Another important feature is that, unlike delegation, the commitment protocol allows for the informed party to make decisions at the interim stage. This form of non-contractibility is particularly appealing when studying international alliances. The Permanent Structured Cooperation (PESCO) agreement, for example, enables this form of decision-making authority to participating countries. The PESCO agreement from 2018 reads, and I quote, “The aim is to jointly develop defence capabilities and make them available for EU military operations....The difference between PESCO and other forms of cooperation is the legally binding nature of the commitments undertaken by the participating Member States. The decision to participate was made voluntarily by each participating Member State, and decision-making will remain in the hands of the participating Member States in the Council.” Clearly, the commitment protocol presented in Section 5 captures this form \textit{autonomy} in decision-

\textsuperscript{31}Notice, however, that at the interim stage the participation constraints are stronger and may not be satisfied. See Forges et al. (2016) and Forges and Horst (2018) for more on communication contracts with interim participation constraints.
making via the inclusion of the non-contractibility constraint.

Another interesting finding is that the value of commitment is increasing as the agents’ interests become more divergent (part (d), Proposition 6). Managing divergent interests is an important component of alliances. In the Iraq war of 2003, the US-Britain alliance faced diverging interests that affected the effectiveness of their joint military exercise. Sir John Chilcott’s *Iraq Inquiry* commissioned in 2009 and published in 2016 notes that diverging interests between US and Britain post-invasion resulted in major hurdles for efficient cooperation between the troops. While the British were shorter-term oriented and focused from very early on how to withdraw their troops from the ground in Iraq, the US military had a more longer-horizon view of the war.\(^{32}\) While such contingencies are difficult to anticipate and commit to ex ante, what the results of Proposition 6 imply is that the gains from committing to binding agreements is higher when the potential for divergence is greater. This is a bit counter-intuitive since usually when countries are more divergent in their goals, the commitment to work together is harder to achieve. The analysis of my paper however shows that the value of commitment is higher precisely when parties are ex ante more divergent.

8 Extensions

Lying costs

The equilibrium in both protocols exhibits some level of lying by the informed agent. Experimental evidence suggests that there is an intrinsic propensity to say the truth even when the information conveyed is soft (Gneezy, 2005; Hurkens and Kartik, 2009), suggesting an aversion to lying. In international alliances, misrepresentation of information

\(^{32}\)In Section 9.8, p 23 of the report, Sir Chilcott records the observation by US’s Gen Jackson: “The perception, right or wrong, in some – if not all – US military circles is that the UK is motivated more by the short-term political gain of early withdrawal than by the long-term importance of mission accomplishment." Also see [https://webarchive.nationalarchives.gov.uk/20171123122743/http://www.iraqinquiry.org.uk/the-report/](https://webarchive.nationalarchives.gov.uk/20171123122743/http://www.iraqinquiry.org.uk/the-report/) for more on the Iraq Inquiry report.
could lead to distrust in diplomatic relations and reputational losses, especially when it is possible to learn about the true state of the world ex-post.

Introducing lying costs (Kartik, 2009) changes the incentives of the informed agent drastically. Suppose, for sake of exposition, lying costs are minimized when the messages are truthful (i.e. \( \mu(\theta) = \theta \)). Then, the presence of lying costs eliminates all but the most informative equilibrium under both simultaneous and sequential protocols. The intuition is that there is now a lying cost associated with wrongful reporting for no marginal benefit in utility. \( A_2 \) incurs a wasteful lying cost by exaggerating, or pooling with the other types and sending \( \bar{m}_p \). This implies that there is an unique separating equilibrium on \([0, \bar{\theta}]\) such that \( \mu(\theta) = \theta \) and the multiplicity problem associated with the baseline model disappears.

What is left to consider is the equilibrium messaging on the pooling interval, \( \bar{m}_p = (\bar{\theta}, \tilde{\theta}] \). One way to interpret my results is by considering them as the limit case of a game with lying costs. As the intensity of lying costs goes to zero, the equilibrium messaging is truthful on \([0, \bar{\theta}]\) and all other types send the message \( \bar{m}_p \). Specifically, when the intensity of lying is very small, there is an incentive to (almost) costlessly exaggerate beyond \( \bar{\theta} \), resulting in no further information transmission. On the other hand, when the lying costs are sufficiently high, there is full separation as the incentives to exaggerate are counteracted by the lying costs.

The interesting case is when the lying costs are sufficiently high but not prohibitively so. It is then possible for alternate equilibrium messaging strategies to emerge. For example, agent \( A_2 \) could bunch state space and send the same (possibly inflated) message for every type in this partition, resulting in clustering of \( A_2 \)'s private information on the interval \( \bar{m}_p \).\(^{33}\)

\(^{33}\)Chen (2011) finds clustering and inflated messaging in a completely different setup. In Chen’s work, there is a small prior probability that an informed sender is honest (always reports truthfully) and the uninformed receiver is naive (always believes the message). This leads to message inflation and clustering at the top end of the message spectrum.
Verifiable Information Disclosure

So far, the analysis has focused mainly on transmission of soft information. In many projects the nature of information is verifiable (Grossman (1981); Milgrom (1981)). The informed agent can disclose verifiable information about project quality, for example. Alternatively, the project contract might specify evidence provision as a requirement. When information can be verified, the incentives for communication change completely. There is unraveling in the sense that $A_2$ would always find it optimal to reveal every state truthfully, leading to full information disclosure even in the presence of action constraints. This is straightforward to observe. On the pooling interval, the highest state $\tilde{\theta}$ is better off disclosing the true type due to the positive spillover effect. By an induction argument, the same holds for types to the left of the highest type. This way, in the limit it follows that every type in $\tilde{m}_p$ would find it optimal to reveal her type truthfully resulting in full disclosure.

9 Conclusion

The paper investigates the role of communication and commitment when there are (one-sided) information asymmetries between agents. When agents’ decisions are substitutable and they face action constraints, under simultaneous decision-making, there is only partial information revelation in equilibrium. There is a positive relationship between amount of information revealed and efficiency, in that welfare of both agents are strictly increasing in the extent of information shared.

The paper considers the case where the uninformed agent has commitment power and the informed agent’s action is non-contractible. With one-sided commitment of this form, the uninformed agent commits to an optimal mechanism that minimizes the miscoordination losses up to a threshold and caps her actions beyond this threshold. The optimal commitment mechanism increases the ex ante expected payoff of both agents.
compared to the simultaneous protocol. The value of commitment is increasing in the divergence of interests between agents and decreasing when the action constraints are weaker.

There are potentially other incentive problems associated with the presence of constraints that are worth exploring. For example, when there is two sided incomplete information, constraints might exacerbate the communication barriers between agents. In fact, as information is more dispersed, the inefficiencies emerging from constraints might worsen leading to decreased welfare. Alternatively, when players instead have a coordination motive with strategic complementarity in actions, constraints might still play a similar role in constraining the credibility of information. Another avenue for future research is to endogenize the investment in the action set. Though constraints were assumed to be exogenous in this paper, it could very well be that agents invest in actions ex ante at some marginal cost. Since the domain of actions available to each player determines the extent of information revealed, this investment decision might differ according to what the underlying decision-making protocol is. All such scenarios require a more detailed analysis, and are left for future work.
A Appendix

A.1 Proof of Theorem 1

In order to establish the equilibrium result some additional notations are required. I will define them in a manner similar to Acemoglu and Jensen (2013), except that they are augmented to incorporate the additional features of the underlying Bayesian game. Let the aggregator for any \( \theta \in \Theta \) be defined as

\[
Q(\theta) = H(h_1(x_1) + h_2(x_2(\theta)))
\]

where \( Q: \Theta \to S \subset \mathbb{R} \) and \( Q(\Theta) = \{Q(\theta) : \theta \in \Theta\} \in 2^S \). Notice that the action of uninformed \( A_1 \) is unaffected by \( \theta \) and is taken in expectation, in any BNE. Since the aggregator is additively separable in the actions of agents the best-responses of any agent can be written purely as a function of the other agents action. Let \( X_1 = h_1(x_1), X_2(\theta) = h_2(x_2(\theta)) \), and \( X_2(\Theta) = \{X_2(\theta) : \theta \in \Theta\} \) for expositional purposes. The reduced best-reply correspondence for the two agents can be written as,

\[
R_1(X_2(\Theta)) = \arg \max_{x_1 \in V} \int_{\theta \in \Theta} U(\tilde{\phi}_1(x_1, H(h_1(x_1) + X_2(\theta))), \theta) \, dF
\]

\[
R_2(X_1, \theta) = \arg \max_{x_2 \in V} U(\tilde{\phi}_2(x_2, H(X_1 + h_2(x_2))), \theta, b)
\]

As before, I define \( R_2(X_1, \Theta) = \{R_2(X_1, \theta) : \theta \in \Theta\} \) to be the collection of best responses for every type of private information of \( A_2 \). Given the \( R_i \)'s, it is possible to define precisely the backward response correspondence \( B_1: 2^S \to 2^V \cup \emptyset \) and \( B_2: S \times \Theta \to 2^V \cup \emptyset \) for the two agents respectively.

\[
B_1(Q(\Theta)) = \left\{ x_1 \in V : x_1 \in R_1\left(\{H^{-1}(Q(\theta)) - h_1(x_1)\}_{\theta \in \Theta}\right) \right\}
\]

\[
B_2(Q(\theta), \theta) = \left\{ x_2 \in V : x_2 \in R_2\left(H^{-1}(Q(\theta)) - h_2(x_2(\theta)), \theta\right) \right\}
\]
In a similar vein, the aggregate backwards response correspondence 
\[ Z: 2^S \times \Theta \to 2^S \cup \emptyset \]
is,
\[ Z(Q(\Theta), \theta) \equiv \{ \psi(x_1, x_2(\theta)) \in S : x_1 \in B_1(Q(\Theta)) \text{ and } x_2(\theta) \in B_2(Q(\theta), \theta) \} \]

\[ Z(Q(\Theta)) = \{ Z(Q(\Theta), \theta) \in 2^S : \theta \in \Theta \} \]
The aggregate correspondence \( Z(Q(\Theta)) \) captures the relationship between the set of action pairs \( X(\theta) = (x_1, x_2(\theta)) \) and the equilibrium aggregates \( Q(\theta) \). The equilibrium of the Bayesian Aggregative game is simply the fixed point of the correspondence \( Z \), i.e. \( Q(\Theta) \in Z(Q(\Theta)) \). Rewriting the (expected) payoffs of the agents in terms of the aggregator function,

\[ \Pi_1(x_1, Q(\Theta)) = \int_{\theta \in \Theta} U\left( \hat{\phi}_1^1(x_1, Q(\theta)), \theta \right) dF \]
\[ \Pi_2(x_2, Q(\theta)|\theta) = U\left( \phi(x_2, Q(\theta)), \theta, b \right) \]
\[ \Pi_2(x_2, Q(\Theta)|\Theta) = \{ \Pi(x_2, Q(\theta)|\theta) \in \mathbb{R} : \theta \in \Theta \} \]
The FOC can be then expressed as follows:

\[ \frac{d\Pi_1(x_1, Q(\Theta))}{dx_1} = \int_{\theta \in \Theta} U_1\left( \hat{\phi}_1^1(x_1, Q(\theta)), \theta \right) \left[ \hat{\phi}_1^1(x_1, Q(\theta)) + \hat{\phi}_2^1(x_1, Q(\theta)) H'(H^{-1}(Q)) \frac{dh_1}{dx_1} \right] dF \]
\[ \frac{d\Pi_2(x_2, Q(\theta)|\theta)}{dx_2} = U_1\left( \hat{\phi}_2^2(x_2, Q(\theta)), \theta, b \right) \left[ \hat{\phi}_1^2(x_2, Q(\theta)) + \hat{\phi}_2^2(x_2, Q(\theta)) H'(H^{-1}(Q)) \frac{dh_2}{dx_2} \right] \]
From both the expressions, it is clear that,

\[ \left[ \hat{\phi}_1^1(x_i, Q(\theta)) + \hat{\phi}_2^1(x_i, Q(\theta)) H'(H^{-1}(Q)) \frac{dh_i}{dx_i} \right] > 0 \]
The functions \( U(.) \) and \( \psi(.) \) are twice continuously differentiable and the action set \( V \) is compact and closed. The last expression above therefore follows directly from the
assumptions on the functional forms of $U$ and $\psi$. Further by construction the best-reply correspondences $R_1(X_2(\Theta))$ and $R_2(X_1, \theta)$ exhibit decreasing selection in $X_2(\Theta)$ and $X_1$ respectively since the game is generalized aggregative and actions are strategic substitutes. The best-reply correspondences are therefore upper hemi-continuous and convex valued. The aggregate $Q(\theta)$ is upper semi-continuous implying that the backward response correspondences ($B_i$) are upper hemi-continuous. Since the backward response correspondence is upper hemi-continuous and the state space is closed and compact, it follows that for any convergent sequences $Q^t(\Theta) \to Q(\Theta)$ and $(Q^t(\Theta), \theta^t) \to (Q(\Theta), \theta)$ it must hold that if $x^1 \in B_1(Q^t(\Theta))$ and $x^2(\theta^t) \in B_2(Q^t(\Theta), \theta^t)$, then given that $B_1$ and $B_2$ have a closed graph (since $R_1$ and $R_2$ have closed graphs), $x_1 \in B_1(Q(\Theta))$ and $x_2(\theta) \in B_2(Q(\Theta), \theta)$. The set valued aggregate correspondence $Z : 2^S \times \Theta \to 2^S \cup \emptyset$ is therefore upper hemi-continuous. Applying Kakutani’s fixed point theorem it is straightforward that the set valued mapping $Z$ has a fixed point (see e.g. Corollary 1 in Jensen (2010)).

Existence implies that there is a collection of $\{(x_1, x_2(\theta))\}_{\theta \in \Theta}$ such that the FOC of the two players are satisfied. This implies that boundary actions $x_1, x_2(\theta) \in \{k, \bar{k}\}$ may be optimal for the agents. To see this, take the case of $A_1$. For a local maxima, it must be that $\frac{d\Pi_1(x_1, Q(\Theta))}{dx_1} = 0$. Since $\left[\phi_1^1(x_1, Q(\theta)) + \phi_2^1(x_1, Q(\theta))H'(H^{-1}(Q))\frac{dH}{dx_1}\right] > 0$, if $U_1$ is everywhere negative for $x_1 = \inf V = k$, then it must be that $\frac{d\Pi_1(x_1, Q(\Theta))}{dx_1} < 0$. However, since the agent is constrained, the boundary strategy is the optimal one. Specifically, $A_1$ may find it optimal to play $k$ and it may be that $\left.\frac{d\Pi_1(x_1, Q(\Theta))}{dx_1}\right|_{x_1 = k} \leq 0$. For any interior strategy $x_1 \in (k, \bar{k})$ to be an equilibrium best-response for $A_1$ the FOC has to hold implying $\Lambda_1(x_1, Q(\Theta)) = \frac{d\Pi_1(x_1, Q(\Theta))}{dx_1} = 0$. Given the concavity assumption on $U$, it follows that the uniform local solvability\footnote{Uniform local solvability implies that when if $\Lambda_1(x_1, Q(\Theta)) = 0 \implies \frac{d\Lambda_1(x_1, Q(\Theta))}{dx_1} < 0$ for all $x_1 \in V$ and $Q(\Theta) \in 2^S$. See Definition 8 in Acemoglu and Jensen (2013) for more.} condition holds satisfying the sufficient condition for a
To prove uniqueness, I will first construct the appropriate equilibrium actions and then show that it must be unique. I will consider equilibrium actions for $A_1$ that are interior, i.e. $x_1 \in (\bar{k}, \tilde{k})$. As stated before, informed agent $A_2$ plays an action for every type of her private information. Given that $b > 0$ and single crossing condition $U_{13} > 0$, the FOC for $A_2$ implies either $U_1 = 0 \ (\tilde{\phi}_1^2(x_2(\theta), Q(\theta))) = \bar{\phi}_2^2$ at $x_2(\theta)$, or $U_1 > 0$ and $x_2(\theta) = \bar{k}$. Let the complete information action for the two players, for any $\theta \in \Theta$, be $(\tilde{x}_1(\theta), \tilde{x}_2(\theta))$ such that $\tilde{\phi}_i(\tilde{x}_i(\theta), \psi(\tilde{x})) \equiv \arg\max_{\tilde{\phi}_i} U(\tilde{\phi}_i, \theta, b_i)$ for both agents. Further, let inf $\Theta = \underline{\theta}$ and sup $\Theta = \overline{\theta}$. Given this, the following lemma provides a structure to the profile of actions in equilibrium.

**Lemma 3.** The equilibrium (interior) action $x_1^e$ of $A_1$ must be such that $\exists \bar{\theta}_e \in (\underline{\theta}, \overline{\theta})$ such that $x_1^e = \tilde{x}_1(\bar{\theta}_e)$.

**Proof.** The proof requires looking at the two extreme cases, i.e. $\theta \in \{\underline{\theta}, \overline{\theta}\}$.

**Case 1.** $x_1^e > \tilde{x}_1(\overline{\theta})$

Since the functions $H$ and $\psi$ are both increasing in $x_i$, it must follow that $x_2(\overline{\theta}) < \tilde{x}_2(\overline{\theta})$.

Let $x_1^b = \tilde{x}_1(\overline{\theta}) + \Delta_1(\overline{\theta})$ and $x_2(\overline{\theta}) = \tilde{x}_2(\overline{\theta}) - \Delta_2(\overline{\theta})$ where both $\Delta_1 > 0$ and $\Delta_2 > 0$. $A_2$ is maximizing her utility which implies that $\tilde{\phi}_2^2 (x_2(\overline{\theta}), \psi(x_1^b, x_2(\overline{\theta}))) = \bar{\phi}_2^2$.

Consider the following equality, $\tilde{\phi}_1^1 (\tilde{x}_1(\overline{\theta}), \psi(\tilde{x}_1(\overline{\theta}), \tilde{x}_2(\overline{\theta}))) = \tilde{\phi}_1^1$. Applying total differentiation to the LHS of this expression,

$$d\tilde{\phi}_1^1 = \frac{\partial \tilde{\phi}_1^1}{\partial x_1} dx_1 + \frac{\partial \tilde{\phi}_1^1}{\partial \psi} d\psi = \frac{\partial \tilde{\phi}_1^1}{\partial x_1} \Delta_1(\overline{\theta}) + \frac{\partial \tilde{\phi}_1^1}{\partial \psi} d\psi$$

Similarly,

$$d\tilde{\phi}_2^2 = \frac{\partial \tilde{\phi}_2^2}{\partial x_2} dx_2 + \frac{\partial \tilde{\phi}_2^2}{\partial \psi} d\psi = -\frac{\partial \tilde{\phi}_2^2}{\partial x_2} \Delta_2(\overline{\theta}) + \frac{\partial \tilde{\phi}_2^2}{\partial \psi} d\psi = 0$$
\[ d\psi = \frac{\partial \tilde{\phi}^2}{\partial x_2} \Delta_2(\tilde{\theta}) \]  

Substituting it into the expression for \( d\tilde{\phi}^1 \),

\[ d\tilde{\phi}^1 = \frac{\partial \tilde{\phi}^1}{\partial x_1} \Delta_1(\tilde{\theta}) + \frac{\partial \tilde{\phi}^2}{\partial x_2} \Delta_2(\tilde{\theta}) > 0 \]

This implies that \( \tilde{\phi}^1(\cdot) > \tilde{\phi}^1_{\theta} \) and \( U_1 < 0 \) for \( A_1 \) when action is above \( \tilde{x}_1(\tilde{\theta}) \). From continuity, this is true for any generic \( \Delta_1(\theta) > 0 \) and \( \Delta_2(\theta) > 0 \) such that \( \theta < \tilde{\theta} \). A similar argument holds for the case when \( x'_1 < \tilde{x}_1(\theta) \).

**Case 2.** \( x'_1 < \tilde{x}_1(\theta) \)

It follows that in this case \( x_2(\theta) > \tilde{x}_2(\theta) \). Let \( x'_1 = \tilde{x}_1(\theta) - \Delta_1(\theta) \) and \( x_2(\theta) = \tilde{x}_2(\theta) + \Delta_2(\theta) \) where both \( \Delta_1 > 0 \) and \( \Delta_2 > 0 \). As previously, \( \tilde{\phi}^2(x_2(\theta), \psi(x'_1, x_2(\theta))) = \tilde{\phi}^2_{\theta} \).

Clearly,

\[ d\tilde{\phi}^1 = -\frac{\partial \tilde{\phi}^1}{\partial x_1} \Delta_1(\tilde{\theta}) - \frac{\partial \tilde{\phi}^2}{\partial x_2} \Delta_2(\tilde{\theta}) < 0 \]

This implies that \( \tilde{\phi}^1(\cdot) < \tilde{\phi}^1_{\theta} \) and \( U_1 > 0 \) for \( A_1 \) when action is below \( \tilde{x}_1(\theta) \). Since the best responses of the agents are upper hemi-continuous, applying intermediate value theorem (Bolzano’s theorem) implies that there must be a \( \theta_e \in [\theta, \tilde{\theta}] \) and \( x'_e \in [\tilde{x}_1(\theta), \tilde{x}_1(\tilde{\theta})] \) such that \( x'_e = \tilde{x}_1(\theta_e) \).

Consider two such equilibrium profile of actions \( E_1 = \{x'_1, (x'_2(\theta))_{\theta \in \Theta}\} \) and \( E_2 = \{x'^2_e, (x'^2_2(\theta))_{\theta \in \Theta}\} \) such that (wlog) \( x'^1_e < x'^2_e \). I claim the following.

**CLAIM.** \( \theta^1_e < \theta^2_e \)

**Proof.** Since the functions \( \psi \) and \( h_i \) are increasing in the actions of the agents and \( \phi^i \) satisfies decreasing selection, it follows that \( x'^1_e < x'^2_e \iff x'_2(\theta) \geq x'^1_2(\theta) \) for all \( \theta \) and there exists an interval \([\theta_e, \theta'_e]\) such that \( x'_2(\theta) > x'^2_2(\theta) \) for all \( \theta \in [\theta, \theta'_e] \) (follows from

47
Further, if for any type \( \theta \) it is true that \( x_2^1(\theta) = x_2^2(\theta) \), then it must be such that \( x_2^1(\theta) = x_2^2(\theta) = \bar{k} \) and \( \bar{\Phi}^2(x_2^1(\theta), \psi(x_1^i(\theta))) < \bar{\Phi}^2_0 \).

There are two cases possible. First, \( x_2^1(\bar{\theta}_c^1) < \bar{k} \) and \( x_2^2(\bar{\theta}_c^2) = \bar{k} \) in which case it is straightforward to observe that from the increasing property of the functions \( \bar{\theta}_1^1 < \bar{\theta}_2^2 \). In the second case, \( x_2^1(\bar{\theta}_c^1) < x_2^2(\bar{\theta}_c^2) < \bar{k} \). In this case it still holds that \( \tilde{\Phi}^1(x_1^1, \psi(x_1^1, x_2^1(\bar{\theta}_c^1))) = \tilde{\Phi}^1_{(\bar{\theta}_c^1)} \) and \( \tilde{\Phi}^1(x_1^2, \psi(x_1^2, x_2^2(\bar{\theta}_c^2))) = \tilde{\Phi}^1_{(\bar{\theta}_c^2)} \). However \( \tilde{\Phi}^1_{(\bar{\theta}_c^1)} < \tilde{\Phi}^1_{(\bar{\theta}_c^2)} \) and single crossing condition \( U_{12} > 0 \) further implies that \( \bar{\theta}_1^1 < \bar{\theta}_2^2 \). □

Split the interval \([\bar{\theta}, \bar{\theta}]\) into three intervals, \([\bar{\theta}, \bar{\theta}_c^1], [\bar{\theta}_c^1, \bar{\theta}_c^2], [\bar{\theta}_c^2, \bar{\theta}]\). Define \( \tilde{\Phi}^1(x_1^1, \theta) \equiv \tilde{\Phi}^1(x_1^1, \psi(x_1^1, x_2^1(\theta))), \tilde{\Phi}^1(x_1^2, \theta) \equiv \tilde{\Phi}^1(x_1^2, \psi(x_1^2, x_2^2(\theta))) \), and \( d_\theta \) as the following:

\[
d_\theta = \tilde{\Phi}^1(x_1^2, \theta) - \tilde{\Phi}^1(x_1^1, \theta)
\]

Consider the three sets separately.

**Case.** \( \theta \in [\bar{\theta}, \bar{\theta}_c^1] \)

From the above arguments, \( x_1^1 < x_1^2 < \bar{x}_1(\theta) \) and \( x_2^1(\theta) < x_2^1(\theta) < \bar{x}_2(\theta) \). Rewriting the above actions as \( x_1^i = \bar{x}_1(\theta) + \Delta_1^i(\theta) \) and \( x_2^i(\theta) = \bar{x}_2(\theta) - \Delta_2^i(\theta) \) where \( i = \{1, 2\} \). It is immediately clear that \( \Delta_1^1(\theta) < \Delta_2^2(\theta) \) and \( \Delta_2^1(\theta) < \Delta_2^2(\theta) \). From Lemma 3, \( \tilde{\Phi}^1(x_1^1, \theta) > \tilde{\Phi}^1_{(\bar{\theta}_c^1)} \) is straightforward to see that \( \Delta_1^1(\theta) = x_1^1 - \bar{x}_1(\theta) \) and \( \Delta_2^2(\theta) = \bar{x}_2(\theta) - x_2^2(\theta) \) are such that the sequences \( (\Delta_1^1(\theta))^n \to \Delta_1^1(\bar{\theta}_c^1) = 0 \), \( (\Delta_2^2(\theta))^n \to \Delta_2^2(\bar{\theta}_c^1) > 0 \), \( (\Delta_2^2(\theta))^n \to \Delta_2^2(\bar{\theta}_c^1) = 0 \), and \( (\Delta_2^2(\theta))^n \to \Delta_2^2(\bar{\theta}_c^1) > 0 \). On the interval \([\bar{\theta}, \bar{\theta}_c^1]\) take the sequence \( (d_\theta)^n \). Given that the sequences \( (\Delta_1^1(\theta))^n \) and \( (\Delta_2^2(\theta))^n \) are convergent, it follows that the sequences \( (\tilde{\Phi}^1(x_1^1, \theta))^n \to \tilde{\Phi}^1_{(\bar{\theta}_c^1)} \) and \( (\tilde{\Phi}^1(x_1^2, \theta))^n \to \tilde{\Phi}^1_{(\bar{\theta}_c^1)} \). Since \( \tilde{\Phi}^1(x_1^1, \theta) = \tilde{\Phi}^1_{(\bar{\theta}_c^1)} \), it follows that \( d_\theta = \tilde{\Phi}^1(x_1^2, \theta) - \tilde{\Phi}^1_{(\bar{\theta}_c^1)} > 0 \). Therefore, the sequence \( (d_\theta)^n \) on the compact set \( S \subset \mathbb{R} \) converges pointwise such that \( (d_\theta)^n \to d_{\bar{\theta}_c^1} \). Finally, \( \tilde{\Phi}^1(x_1^2, \theta) > \tilde{\Phi}^1(x_1^1, \theta) > \tilde{\Phi}^1_{0} \) on this
interval, \( U_1 < 0 \) for \( A_1 \). Since \( U_{11} < 0 \), this further implies that,

\[
U_1 \left( \tilde{\phi}^1(x^e_{1}, \theta), \theta \right) - U_1 \left( \phi^1(x^c_{1}, \theta), \theta \right) < 0 \quad \text{for all} \quad \theta \in [\theta, \tilde{\theta}^1_c)
\] (4)

**Case.** \( \theta \in [\tilde{\theta}^1_c, \tilde{\theta}^2_c) \)

As before, \( \tilde{x}_1(\tilde{\theta}^1_c) = x^c_{1} < x^e_{1} \) and \( \tilde{x}_2(\tilde{\theta}^1_c) = \tilde{x}_2(\tilde{\theta}^1_c) \). Rewriting the actions as \( x^c_{1} = \tilde{x}_1(\theta) - \Delta^1_1(\theta), \quad x^e_{1} = \tilde{x}_1(\theta) + \Delta^1_1(\theta), \quad x^c_{2} = \tilde{x}_2(\theta) - \Delta^2_2(\theta), \) and \( x^e_{2} = \tilde{x}_2(\theta) - \Delta^2_2(\theta) \), it immediately follows that \( \Delta^1_1(\tilde{\theta}^1_c) = \Delta^1_1(\tilde{\theta}^1_c) = 0 \) and \( \Delta^2_2(\tilde{\theta}^2_c) = 0 \). Again from the previous case, we know that \( \tilde{\phi}^1(x^e_{1}, \tilde{\theta}^1_c) > \tilde{\phi}^1(x^c_{1}, \tilde{\theta}^1_c) = \tilde{\phi}^1 \Rightarrow d_{\tilde{\theta}^1_c} > 0 \).

We can then rewrite \((\Delta^1_1(\theta), \Delta^2_2(\theta))\) as the following: \( \Delta^1_1(\theta) = \tilde{x}_1(\theta) - x^c_{1}, \quad \Delta^2_2(\theta) = x^c_{2} - \tilde{x}_1(\theta), \quad \Delta^1_1(\theta) = \tilde{x}_2(\theta) - \tilde{x}_1(\theta), \) and \( \Delta^2_2(\theta) = \tilde{x}_2(\theta) - \tilde{x}_1(\theta) \) such that the sequences \( (\Delta^1_1(\theta))^n \rightarrow \Delta^1_1(\tilde{\theta}^2_c) > 0, \quad (\Delta^2_2(\theta))^n \rightarrow \Delta^2_2(\tilde{\theta}^2_c) = 0, \quad (\Delta^3_3(\theta))^n \rightarrow \Delta^3_3(\tilde{\theta}^2_c) > 0, \) and \( (\Delta^2_2(\theta))^n \rightarrow \Delta^2_2(\tilde{\theta}^2_c) = 0 \). Given that the sequences \((\Delta^1_1(\theta))^n\) and \((\Delta^2_2(\theta))^n\) are convergent, it follows that the sequences \( (\tilde{\phi}^1(x^c_{1}, \theta))^n, (\tilde{\phi}^1(x^e_{1}, \theta))^n \) are such that \( (\tilde{\phi}^1(x^c_{1}, \theta))^n \rightarrow \tilde{\phi}^1(x^c_{1}, \tilde{\theta}^2_c) \) and \( (\tilde{\phi}^1(x^e_{1}, \theta))^n \rightarrow \tilde{\phi}^1(x^e_{1}, \tilde{\theta}^2_c) \). From Lemma 3, \( \tilde{\phi}^1 \rightarrow \tilde{\phi}^1(x^c_{1}, \tilde{\theta}^2_c) > \tilde{\phi}^1(x^e_{1}, \tilde{\theta}^2_c) \Rightarrow d_{\tilde{\theta}^2_c} > 0 \). On the interval \([\tilde{\theta}^1_c, \tilde{\theta}^2_c)\), consider the sequence \((d_{\theta})^n\). It follows that since \( d_{\tilde{\theta}^1_c} = \tilde{\phi}^1(x^c_{1}, \tilde{\theta}^1_c) - \tilde{\phi}^1(x^e_{1}, \tilde{\theta}^1_c) > 0 \) and \( d_{\tilde{\theta}^2_c} = \tilde{\phi}^1(x^c_{1}, \tilde{\theta}^2_c) - \tilde{\phi}^1(x^e_{1}, \tilde{\theta}^2_c) > 0 \), the sequence \((d_{\theta})^n\) converges pointwise such that \( (d_{\theta})^n \rightarrow d_{\tilde{\theta}^2_c} \). Finally, \( \tilde{\phi}^1(x^e_{1}, \theta) > \tilde{\phi}^1(x^c_{1}, \theta) \) on this interval meaning \( U_1 > 0 \) under the action \( x^c_{1} \) and \( U_1 < 0 \) under \( x^e_{1} \) for agent \( A_1 \). This trivially implies that,

\[
U_1 \left( \tilde{\phi}^1(x^e_{1}, \theta), \theta \right) - U_1 \left( \phi^1(x^c_{1}, \theta), \theta \right) < 0 \quad \text{for all} \quad \theta \in [\tilde{\theta}^1_c, \tilde{\theta}^2_c)
\] (5)

**Case.** \( \theta \in [\tilde{\theta}^2_c, \tilde{\theta}] \)

In this case, we can rewrite the equilibrium actions as \( x^c_{1} = \tilde{x}_1(\theta) - \Delta^1_1(\theta), \) and \( x^e_{2} = \tilde{x}_2(\theta) + \Delta^2_2(\theta) \). At \( \theta = \tilde{\theta}^2_c \), the initial conditions on the \( \Delta_i \)'s are \( \Delta^1_1(\tilde{\theta}^2_c) > 0, \quad \Delta^1_1(\tilde{\theta}^2_c) = 0, \quad \Delta^1_1(\tilde{\theta}^2_c) > 0 \) and \( \Delta^2_2(\tilde{\theta}^2_c) = 0 \). We can then rewrite \((\Delta^1_1(\theta), \Delta^2_2(\theta))\) as the following:
\[\Delta^i_1(\theta) = \bar{x}_1(\theta) - x^{e_i}_1 \text{ and } \Delta^i_2(\theta) = x^{i}_2(\theta) - \bar{x}_2(\theta)\] such that the sequences \((\Delta^i_1(\theta))_n \rightarrow \Delta^i_1(\bar{\theta}) > 0\) and \((\Delta^i_2(\theta))_n \rightarrow \Delta^i_2(\bar{\theta}) > 0\). However, we also know that \(\Delta^i_1(\theta) \geq \Delta^i_2(\theta)\) on this interval. Starting from \(d_{\bar{\theta}^2} = \bar{\phi}^1_{\bar{\theta}^2} - \bar{\phi}^1(x^{e_i}_1, \bar{\theta}^2) > 0\), the sequences \((\Delta^i_1(\theta))_n\) and \((\Delta^i_2(\theta))_n\) are convergent implying \((\Delta^i_1(\theta))_n \rightarrow \Delta^i_1(\bar{\theta})\) and \((\Delta^i_2(\theta))_n \rightarrow \Delta^i_2(\bar{\theta})\). Therefore, it follows directly from the preceding observation that the sequences \((\bar{\phi}^1(x^{e_i}_1, \theta))_n, (\bar{\phi}^1(x^{e_2}_1, \theta))_n\) are such that \((\bar{\phi}^1(x^{e_i}_1, \theta))_n \rightarrow \bar{\phi}^1(x^{e_i}_1, \bar{\theta})\) and \((\bar{\phi}^1(x^{e_2}_1, \theta))_n \rightarrow \bar{\phi}^1(x^{e_2}_1, \bar{\theta})\). Given that there is miscoordination on this interval, from Lemma 3 this miscoordination is higher when the action \(x_1\) is smaller, i.e. \(\bar{\phi}^1_1 > \bar{\phi}^1(x^{e_2}_1, \theta) > \bar{\phi}^1(x^{e_i}_1, \theta)\).

Finally, as before, on the interval \([\bar{\theta}^2, \bar{\theta}]\) consider the sequence \((d_{\theta})_n\). It follows that since \(d_{\bar{\theta}^2} = \bar{\phi}^1_{\bar{\theta}^2} - \bar{\phi}^1(x^{e_i}_1, \bar{\theta}^2) > 0\) and \(d_{\bar{\theta}} = \bar{\phi}^1(x^{e_2}_1, \bar{\theta}) - \bar{\phi}^1(x^{e_i}_1, \bar{\theta}) > 0\), the sequence \((d_{\theta})_n\) converges pointwise such that \((d_{\theta})_n \rightarrow d_{\bar{\theta}^2}\). Since \(\bar{\phi}^1_{\bar{\theta}} > \bar{\phi}^1(x^{e_2}_1, \theta) > \bar{\phi}^1(x^{e_i}_1, \theta)\) on this interval meaning \(U_1 > 0\) under both actions \(x_1^{e_i}\) and \(x_1^{e_2}\), and \(U_{11} < 0\), it follows that,

\[U_1(\bar{\phi}^1(x^{e_2}_1, \theta), \theta) - U_1(\bar{\phi}^1(x^{e_i}_1, \theta), \theta) < 0 \text{ for all } \theta \in [\bar{\theta}^2, \bar{\theta}] \tag{6}\]

To conclude the proof for uniqueness, I re-examine the FOC for a maxima for agent \(A_1\) given by the equation,

\[\Lambda_1(x_1, Q(\Theta)) = \int_{\theta \in \Theta} U_1(\bar{\phi}^1(x_1, Q(\theta)), \theta) \left[\bar{\phi}^1_1(x_1, Q(\theta)) + \bar{\phi}^1_2(x_1, Q(\theta))H'(H^{-1}(Q))\left|\frac{dh_1}{dx_1}\right|dF\right] \tag{7}\]

Rewriting the terms in the integral as,

\[\bar{U}_1(x^{e_i}_1, \theta) = U_1(\bar{\phi}^1(x^{e_i}_1, Q(\theta)), \theta) = \]

\[Y(x^{e_i}_1, \theta) = \bar{\phi}^1_1(x^{e_i}_1, Q^{e_i}(\theta)) + \bar{\phi}^1_2(x^{e_i}_1, Q^{e_i}(\theta))\left|\frac{dh_1}{dx_1}\right|_{x_1 = x^{e_i}_1}\]

Given equations 4-6 and the concavity properties of the coordination functions \(\bar{\phi}^i, Q(.)\)
and \((H,h)\),
\[
\bar{U}_1(x^\epsilon_2, \theta) = \bar{U}_1(x^\epsilon_1, \theta) - \delta(\theta) \quad \text{such that} \quad \delta(\theta) > 0
\]
\[
Y(x^\epsilon_2, \theta) = Y(x^\epsilon_1, \theta) - \nu(\theta) \quad \text{such that} \quad \nu(\theta) > 0
\]

Therefore if \(x^\epsilon_1\) is indeed an equilibrium,
\[
\int_{\theta \in \Theta} \bar{U}_1(x^\epsilon_1, \theta)Y(x^\epsilon_1, \theta)dF = 0
\]

Similarly, if \(x^\epsilon_2\) is also an equilibrium,
\[
\int_{\theta \in \Theta} (\bar{U}_1(x^\epsilon_1, \theta) - \delta(\theta)) \cdot (Y(x^\epsilon_1, \theta) - \nu(\theta))dF < 0
\]

This is valid for any two equilibria that satisfy the conditions for a local maxima. Therefore the equilibrium actions are unique. \(\text{QED}\)

### A.2 Proof of Theorem 2

#### Sufficiency

Suppose HTIC condition was satisfied. Then the following statements hold true under truthful messaging \(m(\theta) \in M_0\) by \(A_2\):

\[
\tilde{x}_1(\theta) = x^*_1(\theta) \equiv \arg \max_{x_1 \in V} U \left( \phi^1(x_1, x^*_2(\theta)), \theta \right) \quad \text{for all} \quad \theta \in \Theta \setminus \tilde{\theta}
\]
\[
\tilde{x}_2(\theta) = x^*_2(\theta) \equiv \arg \max_{x_2 \in V} U \left( \phi^2(x_2, x^*_1(\theta)), \theta, b \right) \quad \text{for all} \quad \theta \in \Theta \setminus \tilde{\theta}
\]
\[
\phi^2(\tilde{x}_2(\theta), \tilde{x}_1(\theta)) = \phi^2(x^*_2(\theta), x^*_1(\theta)) = \bar{\phi}_0 \quad \text{for all} \quad \theta \in \Theta \setminus \tilde{\theta}
\]

The first equivalence is due to the uniqueness of best responses and the fact that \(x^*_1(\theta) < \bar{k}\) for \(\theta \in \Theta \setminus \tilde{\theta}\) by single crossing property of the utility function \((U_{12} > 0)\). The second
follows immediately from HTIC and the first condition being satisfied. The last equality trivially holds true. This ensures there is no inefficiency and $A_2$ always achieves first best levels of coordination for all $\theta$. Hence, there exists an equilibrium in which there is full separation and information is completely revealed.

**Necessity**

Suppose there is full separation but HTIC is violated, i.e. $\bar{x}_2(\bar{\theta}) > \bar{k}$.

**CLAIM.** $\exists \bar{\theta} < \tilde{\theta} : \bar{x}_2(\bar{\theta}) = x_2^*(\bar{\theta}) = \bar{k}$

**Proof.** We know that for any two $\theta_1, \theta_2 \in \Theta$ such that $\theta_1 \neq \theta_2, \bar{x}_2(\theta_1) \neq \bar{x}_2(\theta_2)$. This follows from continuity and single crossing property of the utility functions. Since $\bar{x}_2(\bar{\theta}) > k$ and $\bar{x}_2(\tilde{\theta}) > \bar{k}$, and the fact that the sequence $(\bar{x}_2(\theta))^n \rightarrow \bar{x}_2(\theta)$ (pointwise convergent), implies there must exist a subsequence $(\bar{x}_2(\theta))^m, m < n$ converging to $\bar{k}$. This immediately implies $(\bar{x}_2(\theta))^m \rightarrow \bar{k} = \bar{x}_2(\tilde{\theta})$.

Consider the set of types $\theta \in (\bar{\theta}, \tilde{\theta}]$. Since $\bar{x}_2(\theta) > \bar{k}$, it directly follows that the equilibrium actions are such that $x_2^*(\theta) = \bar{k}$. This further means that,

$$x_1^*(\theta) \equiv \arg\max_{x_1 \in V} U(\phi_1(x_1, \bar{k}), \theta) > \bar{x}_1(\theta)$$

To construct the appropriate sequences, let the equilibrium actions $x_i^*(\theta)$ be written as,

$$x_1^*(\theta) = \bar{x}_1(\theta) + \kappa_1(\theta)$$

$$x_2^*(\theta) = \bar{x}_2(\theta) - \kappa_2(\theta)$$

Notice that $A_1$'s equilibrium actions are readjusted according to $\bar{x}_1(\theta)$ while $A_2$'s actions are indexed to $\bar{x}_2(\theta)$. This immediately implies that $\kappa_1(\theta) > 0$ and $\kappa_2(\theta) > 0$ are both
increasing in $\theta$. The readjusted action for $A_1$ solves the following,

$$x_1^*(\theta) \equiv \arg\max_{x_1 \in V} U(\phi^1(x_1, \bar{k}), \theta) \quad \text{for all } \theta \in (\bar{\theta}, \tilde{\theta}]$$

This is equivalent to choosing a $x_1$ such that $\phi^1(x_1, \bar{k}) = \tilde{\phi}_0^1$. That is, the uninformed agent anticipates that $A_2$’s action is constrained by $\bar{k}$ and best responds to that. Since $A_1$ achieves $\tilde{\phi}_0^1$ irrespective of whether $A_2$’s action is $x_2(\theta)$ or $x_2^*(\theta) = \bar{k}$, total differentiation of the $\phi^j$’s at any $\theta \in (\bar{\theta}, \tilde{\theta}]$ yields the following:

$$\frac{d\phi^1}{d\theta} = \frac{\partial \phi^1}{\partial x_1} dx_1 + \frac{\partial \phi^1}{\partial x_2} dx_2$$

$$\frac{d\phi^1}{d\theta} = \frac{\partial \phi^1}{\partial x_1} \kappa_1(\theta) - \frac{\partial \phi^1}{\partial x_2} \kappa_2(\theta) = 0$$

$$\Rightarrow \kappa_1(\theta) = \frac{\frac{\partial \phi^1}{\partial x_2}}{\frac{\partial \phi^1}{\partial x_1}} \kappa_2(\theta)$$

Since $\frac{\partial \phi^1}{\partial x_2} < \frac{\partial \phi^1}{\partial x_1}$, it directly implies that $\kappa_1(\theta) < \kappa_2(\theta)$. Totally differentiating $\phi^2$ gives,

$$\frac{d\phi^2}{d\theta} = \frac{\partial \phi^2}{\partial x_2} dx_2 + \frac{\partial \phi^2}{\partial x_1} dx_1$$

$$\frac{d\phi^2}{d\theta} = -\frac{\partial \phi^2}{\partial x_2} \kappa_2(\theta) + \frac{\partial \phi^2}{\partial x_1} \kappa_1(\theta)$$

Again the fact that $\kappa_1(\theta) < \kappa_2(\theta)$ and $\frac{\partial \phi^2}{\partial x_1} < \frac{\partial \phi^2}{\partial x_2}$ implies that $d\phi^2 < 0$ when the actions are constrained, i.e. $\phi^2(\bar{k}, x_1^*(\theta)) < \tilde{\phi}_0^2$ on this interval.

$$\phi^2(\bar{k}, \bar{x}_1(\theta)) < \phi^2(\bar{k}, x_1^*(\theta)) < \phi^2(\bar{x}_2(\theta), \bar{x}_1(\theta)) = \tilde{\phi}_0^2$$

The first inequality is due to Assumption 3 and the second follows from the above arguments. Given these profile of actions under full separation, all we need to show is a profitable deviation for any $\theta \in (\bar{\theta}, \tilde{\theta}]$. Suppose, wlog, $\theta$ pretends to be a higher type
$\theta + \epsilon$ such that,

$$x^*_1(\theta + \epsilon) \equiv \operatorname{argmax}_{x_1 \in V} U \left( \phi^1(x_1, \bar{k}), \theta \right)$$

From earlier arguments, we know that $\phi^1(x^*_1(\theta + \epsilon), \bar{k}) = \bar{\phi}^1_{\theta + \epsilon}$. Further, $x^*_1(\theta + \epsilon) = \bar{x}_1(\theta + \epsilon) + \kappa_1(\theta + \epsilon) > x^*_1(\theta)$. The deviation action for $A_2$ with private information $\theta$ but pretends to be $\theta + \epsilon$, given by $x^d_2(\theta, \theta + \epsilon)$ is,

$$x^d_2(\theta, \theta + \epsilon) \equiv \operatorname{argmax}_{x_2 \in \mathcal{R}} U \left( \phi^2(x_2, x^*_1(\theta + \epsilon)), \theta, b \right)$$

Notice that the optimal deviation action is unconstrained ($x_2 \in \mathcal{R}$) similar to $\bar{x}_1(\theta)$. There are two possible cases for the optimal deviation action. I consider both of them below.

**Case.** $x^d_2(\theta, \theta + \epsilon) \leq \bar{k} \implies x^*_2(\theta, \theta + \epsilon) = x^d_2(\theta, \theta + \epsilon)$

Trivially this implies $\bar{\phi}^2_{\theta} = \phi^2 \left( x^*_2(\theta, \theta + \epsilon), x^*_1(\theta + \epsilon) \right) > \phi^2 \left( \bar{k}, x^*_1(\theta) \right)$. Therefore the deviation is profitable.

**Case.** $x^d_2(\theta, \theta + \epsilon) > \bar{k} \implies x^*_2(\theta, \theta + \epsilon) = \bar{k}$

In this case, clearly the following inequalities hold:

$$\bar{\phi}^2_{\theta} = \phi^2 \left( x^d_2(\theta, \theta + \epsilon), x^*_1(\theta + \epsilon) \right) > \phi^2 \left( \bar{k}, x^*_1(\theta + \epsilon) \right) > \phi^2 \left( \bar{k}, x^*_1(\theta) \right) = \phi^2 \left( \bar{k}, \bar{x}_1(\theta) + \kappa_1(\theta) \right)$$

The first inequality is obviously true. The second follows from the positive spillover assumption and the fact that $x^*_1(\theta + \epsilon) > x^*_1(\theta)$. Therefore, by deviating from full separation and sending a message $m(\theta) \in M_{\theta + \epsilon}$, the informed agent is able to reduce the miscoordination as $\phi^2 \left( \bar{k}, x^*_1(\theta + \epsilon) \right)$ is closer to $\bar{\phi}^2_{\theta}$. Since $U_1$ is increasing, this implies that,

$$U \left( \phi^2 \left( \bar{k}, x^*_1(\theta + \epsilon) \right), \theta, b \right) > U \left( \phi^2 \left( \bar{k}, x^*_1(\theta) \right), \theta, b \right)$$

Therefore under full separation and when HTIC condition does not hold, there are always types for whom there is a profitable deviation, precluding separation. This com-
pletes the proof.

QED

A.3 Proof of Lemma 1

Suppose not and there exists an equilibrium messaging strategy in which there are two partitions (wlog), \((\theta', \theta_g)\) and \((\theta_g, \theta'')\) such that \(\theta_g \in G\) and \(\theta'' > \theta_g\). (I do not impose any further restrictions on \(\theta'\) and \(\theta''\).) Let the messages associated with the two partitions be \(m_1\) and \(m_2\). For purposes of this proof, I will refer to the messages as characterizing the set of types sending them, i.e. \(m_1 = (\theta', \theta_g)\) and \(m_2 = (\theta_g, \theta'')\). I will show that the type \(\theta_g\) will prefer to send the higher message \(m_2\).

The equilibrium action of the agents under the two pooling messages are,

\[
x_1^*(m_i) \equiv \arg\max_{x_1 \in V} \int U\left(\phi^1(x_1, x_2^*(\theta, m_i)), \theta\right) dP(\theta|m_i)
\]

\[
x_2^*(\theta, m_i) \equiv \arg\max_{x_2 \in V} U\left(\phi^2(x_2, x_1^*(m_i)), \theta, b\right)
\]

CLAIM. The action of \(A_1\) is such that \(x_1^*(m_1) < x_1^*(\theta_g)\) and \(x_1^*(m_2) < x_1^*(\theta'')\).

Proof. Consider the action of \(A_1\) under \(\bar{m}_1\). Suppose \(x_1^*(\bar{m}_1) = x_1^*(\theta_g) \equiv \arg\max_{x_1 \in V} U\left(\phi^1(x_1, k), \theta_g\right)\). We know from previous arguments in Theorem 2 that \(\bar{x}_2(\theta_g) > \bar{k}\) which implies that \(x_2^*(\theta_g) = \bar{k}\) and \(x_1^*(\theta_g) \equiv \arg\max_{x_1} U\left(\phi^1(x_1, \bar{k}), \theta_g\right) > \bar{x}_2(\theta_g)\). Take the type \(\theta'\). If the best response of \(A_2\) given the action \(x_1^*(\theta_g)\) is such that,

\[
x_2^*(\theta', \bar{m}_1) \equiv \arg\max_{x_2 \in V} U\left(\phi^2(x_2, x_1^*(\theta_g)), \theta', b\right)
\]

Then there are two cases to consider.

Case. \(x_2^*(\theta', \bar{m}_1) = \bar{k}\)

From single crossing, for all \(\theta \in \bar{m}_1\) it holds that \(x_2^*(\theta) = \bar{k}\) and trivially for all \(\theta \in \bar{m}_1 \setminus \{\theta_g\}\), \(\phi^1_{\theta_g} = \phi_1(x_1^*(\theta_g), \bar{k}) > \bar{\phi}_\theta \implies U_1 < 0\) on this interval for \(A_1\). Therefore
\[ x^*_1(\bar{m}_1) < x^*_1(\theta_s). \]

**Case.** \( x^*_2(\theta', \bar{m}_1) < \bar{k} \)

In this case, take the sequence of \( (x^*_2(\theta, \bar{m}_1))^n \rightarrow \bar{k}. \) From continuity of the payoff function, clearly the set of types for which \( x^*_2 = \bar{k} \) is compact and closed. Let \( \bar{\theta}_1 = \inf G_1 \equiv \{ \theta : x^*_2(\theta, \bar{m}_1) = \bar{k} \}. \) For all the types in \( G_1, \phi^1(x^*_1(\theta_s), \bar{k}) > \bar{\phi}^1_\theta \Longleftrightarrow U_1 < 0 \) for \( A_1 \) and \( \phi^2(\bar{k}, x^*_1(\theta_s)) \leq \bar{\phi}^2 \Longleftrightarrow U_1 \geq 0 \) for \( A_2. \) At \( \bar{\theta}_1, \phi^1(x^*_1(\theta_s), \bar{k}) > \bar{\phi}^1_{\bar{\theta}_1} \) and \( \phi^2(\bar{k}, x^*_1(\theta_s)) = \bar{\phi}^2. \)

\[ \phi^1_d(\theta) = \phi^1(x^*_1(\theta_s), x^*_2(\theta, \bar{m}_1)) - \bar{\phi}^1_\theta \]

\( \phi^1_d(\theta) \) captures the extent of miscoordination on the interval \((\theta', \bar{\theta}_1). \) The sequence of equilibrium actions of \( A_2 \) starting from \( (x^*_2(\bar{\theta}_1, \bar{m}_1)) \) is convergent, i.e. \( (x^*_2(\theta, \bar{m}_1))^n \rightarrow (x^*_2(\theta', \bar{m}_1)) < \bar{k}. \) The decreasing sequence \( (x^*_2(\theta, \bar{m}_1))^n \) is convergent implies that \( (\bar{\phi}^2_n) \rightarrow (\bar{\phi}^2_\theta). \) Since both \( \phi^i \)'s are continuous, \( d\bar{\phi}^1_\theta = d\bar{\phi}^2_\theta. \) However,

\[ d\phi^1 = \frac{\partial \phi^1}{\partial x_1}dx_1 + \frac{\partial \phi^1}{\partial x_2}dx_2 < \frac{\partial \phi^2}{\partial x_2}dx_2 = d\phi^2 \]

That is, the rate of convergence of \( \phi^1 \) is slower than that of \( \phi^2 \) due to imperfect substitutability of actions. Therefore the miscoordination term for \( A_1, \) given by \( \phi^1_d(\theta) \theta \in (\theta', \bar{\theta}_1), \) where \( \phi^1_d(\bar{\theta}_1) > 0 \) is bounded away from zero. That is \( \phi^1_d(\theta) \rightarrow \phi^1_d(\theta') > 0. \) Therefore \( U_1 < 0 \) for \( A_1 \) on this interval as well. This completes the proof. \( \square \)

**CLAIM.** \( x^*_1(\bar{m}_1) < x^*_1(\bar{m}_2). \)

**Proof.** Suppose \( x^*_1(\bar{m}_2) = x^*_1(\bar{m}_1). \) Then, since \( x^*_1(\bar{m}_1) < x^*_1(\theta_s) \) it implies that for all \( \theta \in \bar{m}_2, x^*_2(\theta) = \bar{k} \) and \( \phi^1(x^*_1(\bar{m}_1), \bar{k}) < \bar{\phi}^1_{\theta_s} < \bar{\phi}^1_\theta \) (single crossing). This further implies \( U_1 > 0 \) over the whole interval and there is a profitable deviation for \( A_1 \) at \( x_2 = x^*_1(\bar{m}_1). \) \( \square \)

Now, all we need to show is that the indifference condition at \( \theta_s \) breaks down. That is,

\[ \phi^2(\bar{k}, x^*_1(\bar{m}_1)) < \phi^2(x^*_2(\theta_s, \bar{m}_2), x^*_1(\bar{m}_2)) < \bar{\theta}^2_{\theta_s}. \]

56
Where the first term is the coordination function for $\theta_g$ type $A_2$ under the pooling message $\bar{m}_1 (x_1^*(\bar{m}_1) = \bar{k})$. To show that the above inequality holds, we define $x_2^*(\theta_g, \bar{m}_2)$ as the following,

$$x_2^*(\theta_g, m_2) \equiv \arg\max_{x_2 \in V} U \left( \phi^2(x_2, x_1^*(\bar{m}_2)), \theta, b \right)$$

If $x_2^*(\theta_g, \bar{m}_2) < \bar{k}$ then $\phi^2 \left( x_2^*(\theta_g, \bar{m}_2), x_1^*(\bar{m}_2) \right) = \bar{\phi}^g_{\theta_g}$ in which case sending the message is clearly better for $\theta_g$ type in that,

$$U \left( \bar{\phi}^g_{\theta_g}, \theta_g \right) > U \left( \phi^2(\bar{k}, x_1^*(\bar{m}_1)), \theta_g \right)$$

Alternately, if $x_2^*(\theta_g, \bar{m}_2) = \bar{k}$ then $\phi^2 \left( \bar{k}, x_1^*(\bar{m}_1) \right) < \phi^2 \left( \bar{k}, x_1^*(\bar{m}_2) \right) < \bar{\phi}^g_{\theta_g}$ since there is positive spillover at $\theta_g$. This is valid for any pair of $(\theta', \theta'')$ as long as $\theta'' > \theta_g$. This completes the proof. QED

### A.4 Proof of Theorem 3

Consider the following set of strategies for the agents for a given threshold $\theta^*$:

- **(Equilibrium path)** If $\bar{m} \in \bigcup_{\theta \in \Theta \setminus [\theta^* \cup \theta]} M_\theta$: $x_1^*(\theta) = \bar{x}_1(\theta)$ and $x_2^*(\theta) = \bar{x}_2(\theta)$

- If $\bar{m} = \bar{m}$:
  
  - $x_1^*(\bar{m}) \equiv \arg\max_{x_1 \in V} \int_{\theta \in \Theta \setminus [\theta^* \cup \theta]} U \left( \phi^1(x_1, x_2^*(\theta, \bar{m})), \theta \right) dP(\theta | \bar{m})$
  
  - $x_2^*(\theta, \bar{m}) \equiv \arg\max_{x_2 \in V} U \left( \phi^2(x_2, x_1^*(\bar{m})), \theta, b \right)$

- **(Off equilibrium path)** If $\bar{m} \in \bigcup_{\theta \in \Theta \setminus [\theta^* \cup \theta]} M_\theta$: $p(\theta^* | \bar{m}) = 1$

  - $x_1^*(\bar{m}) = x_1^*(\theta^*)$
  
  - $x_2(\theta, \bar{m}) \equiv \arg\max_{x_2 \in V} U \left( \phi^2(x_2, x_1^*(\bar{m})), \theta, b \right)$
In the PRTE defined above there is a region of separation $[\theta^*, \theta^+]$ and a region of pooling where all types above the cutoff $\theta^*$ send the same message $\bar{m}$. Clearly, on the separating interval both agents achieve their (unique) first best $\bar{\phi}^i_\theta$ and cannot do better. The off-equilibrium beliefs are constructed such that any message that is not a separating one or $\bar{m}$ is believed to be from $\theta^*$, the highest separating type. To show that this constitutes an equilibrium, I characterize the equilibrium response of the agents under $\bar{m}$ in the following lemma.

**Lemma.** For any information threshold $\theta^*$, agent $A_1$’s equilibrium action on receiving the message $\bar{m} = (\theta^*, \bar{\theta})$ is given by $x_1^*(\bar{m})$ that solves,

$$\arg\max_{x_1 \in V} \int_{\theta^*}^{\theta^+} U \left( \phi^1(x_1, x_2^*(\theta, \bar{m})), \theta \right) dP(\theta | \bar{m}) + \int_{\bar{\theta}}^{\theta^+} U \left( \phi^1(x_1, \bar{k}), \theta \right) dP(\theta | \bar{m})$$

(8)

**Proof.** The lemma states that there is a cutoff state $\theta^*_s$ such that for all $\theta \in (\theta^*, \theta^+_s]$ the best response of $A_2$ is within the constraint $\bar{k}$ (i.e. $\phi^2(x_2^*(\theta, \bar{m}), x_1^*(\bar{m})) = \bar{\phi}^2_{\theta}$). For the remaining types in the pooling interval $\theta \in \bar{m} \setminus (\theta^*, \theta^+_s]$, $x_2^*(\theta, \bar{m}) = \bar{k}$. Define $x_1^{fb}(\bar{\theta}) \equiv \arg\max_{x_1 \in V} U \left( \phi^2(\bar{k}, x_1), \bar{\theta}, b \right)$ as the action of $A_1$ that provides first best levels of coordination function to $A_2$ when the type is $\bar{\theta}$, i.e. $\phi^2(\bar{k}, x_1^{fb}(\bar{\theta})) = \bar{\phi}^2_{\bar{\theta}}$.

To prove the lemma, it suffices to prove that $x_1^*(\bar{m}) < x_1^{fb}(\bar{\theta})$. The inequality follows directly from noting that if $x_1^*(\bar{m}) = x_1^{fb}(\bar{\theta})$, then for all $\theta \in \bar{m}$, $x_2^*(\theta, \bar{m}) < \bar{k}$ and $\phi(x_1^{fb}(\bar{\theta}), \bar{k}) > \bar{\phi}^1_{\bar{\theta}}$, from single crossing and continuity. However, as argued earlier (see Lemma 1), this also implies that $\phi^1(x_1^{fb}(\bar{\theta}), x_2^*(\theta, \bar{m})) > \bar{\phi}^1_{\bar{\theta}}$ for all $\theta \in \bar{m}$ due to imperfect substitutability of agents’ actions. Therefore there must exist a $\theta^*_s \in (\theta^*, \bar{\theta})$. This completes the proof.

Given the nature of best responses described above, it immediately implies that for $A_2$, all types in $(\theta^*, \theta^+_s]$ achieve first best levels of coordination under the pooling message and therefore are at least weakly better off. For all the types in $(\theta^*_s, \bar{\theta})$, $x_2^*(\theta, \bar{m}) = \bar{k}$ and
\( \phi_0^2 > \phi_1^2 (\bar{k}, x_1^*(m)) > \phi_2^2 (\bar{k}, x_1^*(\theta^*)) \). Since \( U_1 > 0 \) on this interval it immediately follows that when the action of \( A_1 \) is higher it is strictly better for \( A_2 \) (positive spillover effect).

This completes the proof. \( \text{QED} \)

A.5 Proof of Proposition 1

Take any PRTE with threshold \( \theta^* \). I make the following claim.

Claim: \( \forall \theta' \in (0, \theta^*), \exists \epsilon > 0 : \forall \theta \in (\theta' - \epsilon, \theta') \),

\[
U \left( \phi^2 \left( x_2^*(\theta), x_1^*(\theta) \right), \theta, b \right) = U \left( \phi^2 \left( x_2^*(\theta', m_{(\theta' - \epsilon, \theta')}), x_1^*(m_{(\theta' - \epsilon, \theta')}) \right), \theta, b \right)
\]

Where the message \( m_{(\theta' - \epsilon, \theta')} \) simply implies that the type is in the interval \( (\theta' - \epsilon, \theta') \).

The claim just states that for any separating type \( \theta' \), it is possible to find a pooling interval of types \( m_{\text{pool}} = m_{(\theta' - \epsilon, \theta')} \) such that the indifference condition holds for all types within this interval, i.e. each of the types in the pooling interval is indifferent between the separating message and the pooling one. The indifference (IC) condition merely requires that \( A_2 \) is able to achieve \( \bar{\phi}_0^S \) which is possible as long as best responses are within the constraints.

To show this, all we need to check for are the indifference conditions of the boundary types \( \theta' - \epsilon \) and \( \theta' \),

\[
U \left( \phi^2 \left( x_2^*(\theta'), x_1^*(\theta') \right), \theta', b \right) = U \left( \phi^2 \left( x_2^*(\theta', m_{(\theta' - \epsilon, \theta')}), x_1^*(m_{(\theta' - \epsilon, \theta')}) \right), \theta', b \right)
\]

\[
U \left( \phi^2 \left( x_2^*(\theta' - \epsilon), x_1^*(\theta' - \epsilon) \right), \theta' - \epsilon, b \right) = U \left( \phi^2 \left( x_2^*(\theta' - \epsilon, m_{(\theta' - \epsilon, \theta')}), x_1^*(m_{(\theta' - \epsilon, \theta')}) \right), \theta' - \epsilon, b \right)
\]

The latter condition follows from noting that any upward deviation is always within the domain of available actions (from Assumption 5). That is, \( x_1^*(\theta' - \epsilon) > x_1^*(m_{(\theta' - \epsilon, \theta')}) \) from single crossing \( (U_{12} > 0) \) and \( x_2^*(\theta' - \epsilon) < x_2^*(\theta' - \epsilon, m_{(\theta' - \epsilon, \theta')}) \) due to imperfect sub-
stutability. However, \( \phi^2 \left( x_2^*(\theta' - \epsilon), x_1^*(\theta' - \epsilon) \right) = \phi^2 \left( x_2^*(\theta' - \epsilon, m_{(\theta' - \epsilon, \theta')}), x_1^*(m_{(\theta' - \epsilon, \theta')}) \right) = \tilde{\phi}_{\theta' - \epsilon}^2 \) meaning that \( A_2 \) achieves first best levels of coordination function for the type \( \theta' - \epsilon \) irrespective of whether the message is a separating or pooling one.

The former condition states that the type \( \theta' \) would pool with lower types and be indifferent from separating. To see this, notice that \( x_2^*(\theta') = k' < \bar{k} \) under a separating (truthful) message. By continuity, there must exist a \( \epsilon \)-deviation such that the \( x_2^*(\theta', m_{(\theta' - \epsilon, \theta')}) \in (k', \bar{k}] \). If this were not true, then \( \lim_{\epsilon \to 0} x_2^*(\theta', m_{(\theta' - \epsilon, \theta')}) = k' < \bar{k} \), a contradiction. As before, since \( x_2^*(\theta') < x_2^*(\theta', m_{(\theta' - \epsilon, \theta')}) \) it follows (from Assumption 3 and SC) that \( x_1^*(\theta') > x_1^*(m_{(\theta' - \epsilon, \theta')}) \) but \( \phi^2 (x_2^*(\theta'), x_1^*(\theta')) = \phi^2 (x_2^*(\theta', m_{(\theta' - \epsilon, \theta')}), x_1^*(m_{(\theta' - \epsilon, \theta')})) = \tilde{\phi}_{\theta'}^2 \). If not, \( A_2 \) can always increase actions up to the point where it achieves first best. This completes the proof. **QED**

### A.6 Proof of Proposition 2

Let \( W_1(\theta^*) \) and \( W_2(\theta^*) \) be the ex ante welfare of the two agents respectively. I will write them down in terms of the cutoff threshold \( \theta^* \).

**A1 Welfare:**

\[
W_1(\theta^*) = \int_{\theta}^{\theta^*} U \left( \phi^1 (x_1^*(\theta), x_2^*(\theta)), \theta \right) dF(\theta) + \int_{\theta}^{\theta^*} U \left( \phi^1 (x_1^*(\bar{\theta}), x_2^*(\bar{\theta})), \theta \right) dF(\theta)
\]

Taking the derivative of \( A_1 \)'s welfare with respect to \( \theta^* \),

\[
\frac{dW_1(\theta^*)}{d\theta^*} = \left[ U \left( \phi^1 (x_1^*(\theta^*), x_2^*(\theta^*)), \theta^* \right) - U \left( \phi^1 (x_1^*(\bar{\theta}), x_2^*(\theta^*)), \theta^* \right) \right] f(\theta^*) > 0
\]

for any \( \theta^* \leq \bar{\theta} \) since \( \phi^1 (x_1^*(\theta^*), x_2^*(\theta^*)) = \tilde{\phi}_{\theta^*}^1 \), the first best levels of coordination. Fur-
ther, there is a discontinuous jump at \( \theta^* \) following a pooling message, implying that

\[
|\phi^1(x^*_1(\theta^*), x^*_2(\theta^*)) - \phi^1(x^*_1(\bar{m}), x^*_2(\theta^*, \bar{m}))| > 0 \text{ at } \theta^*.
\]

\[ A_2 \] Welfare:

Take any two cutoff equilibria \( \theta^1, \theta^2 \leq \bar{\theta} \), call them PRTE\(_1\) and PRTE\(_2\), such that \( \theta^1 < \theta^2 \) (wlog). Let the corresponding pooling messages associated with the PRTE be \( \bar{m}^1 = (\theta^1, 1) \) and \( \bar{m}^2 = (\theta^2, 1) \) respectively. I will establish that \( A_2 \) is better off with the more informative equilibrium \( \theta^2 \). Similar to arguments made in A.4, for cutoff equilibria \( \theta^1, \theta^2 \) there exists a corresponding \( \theta^1_s \) and \( \theta^2_s \) such that \( x^*_2(\theta^1_s, \bar{m}^1) = x^*_2(\theta^2_s, \bar{m}^2) = \bar{k} \). From single crossing property, \( A_1 \)'s action must be higher for the pooling message \( \bar{m}^2 \) corresponding to the threshold \( \theta^2 \), i.e. \( x^*_1(\bar{m}^2) > x^*_1(\bar{m}^1) \). If this is true, then \( \theta^1_s < \theta^2_s \). Suppose not, and \( \theta^1_s > \theta^2_s \). Then, \( x^*_2(\theta^2_s, \bar{m}^1) < x^*_2(\theta^1_s, \bar{m}^1) = \bar{k} \). But \( x^*_2(\theta^2_s, \bar{m}^2) \geq x^*_2(\theta^2_s, \bar{m}^2) = \bar{k} \). This is a contradiction. Therefore the claim holds. In order to prove the result for \( A_2 \), I consider two possible scenarios.

**Scenario (a):** When \( \theta^1_s < \theta^2_s \). That is, \( \theta^1 < \theta^1_s < \theta^2 < \theta^2_s \). The welfare to \( A_2 \) under the two PRTE’s is given by,

\[
W_2(\theta^1) = \int_0^{\theta^1} U \left( \phi^2(x^*_2(\theta), x^*_1(\theta)), \theta, b \right) dF + \int_0^{\bar{\theta}} U \left( \phi^2(x^*_2(\theta, \bar{m}^1), x^*_1(\bar{m}^1)), \theta, b \right) dF
\]

\[
W_2(\theta^2) = \int_0^{\theta^2} U \left( \phi^2(x^*_2(\theta), x^*_1(\theta)), \theta, b \right) dF + \int_0^{\bar{\theta}} U \left( \phi^2(x^*_2(\theta, \bar{m}^2), x^*_1(\bar{m}^2)), \theta, b \right) dF
\]

Under PRTE\(_1\), \( A_2 \)'s equilibrium action is within the bound for the interval \((0, \theta^1_s]\). Since \( \theta^1_s < \theta^2_s \), \( A_2 \)'s action is also within the bound over the interval \((0, \theta^1_s]\) under PRTE\(_2\).
Therefore, what is left to be checked are those states in which the constraints are binding for $A_2$. In $PRTE_1$, this corresponds to the interval $(\theta_s^1, 1]$. On the same interval, I compare the expected (ex ante) utility under $PRTE_2$. I will refer to this utility as the residual welfare that results from inefficiency, $W^{RES}_2(\theta^1)$ and $W^{RES}_2(\theta^1)$ respectively.

\[
W^{RES}_2(\theta^1) = \int_{\theta_s^1}^{\theta_s^2} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^1)\right), \theta, b\right) dF + \int_{\theta_s^2}^{\theta} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^1)\right), \theta, b\right) dF
\]

\[
W^{RES}_2(\theta^2) = \int_{\theta^1}^{\theta^2} U\left(\phi^2\left(x_2^* (\theta), x_1^* (\theta)\right), \theta, b\right) dF + \int_{\theta^2}^{\theta^2} U\left(\phi^2\left(x_2^* (\theta, \bar{m}^2), x_1^* (\bar{m}^2)\right), \theta, b\right) dF
\]

\[
+ \int_{\theta^2}^{\theta} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^2)\right), \theta, b\right) dF
\]

Taking the expression $W^{RES}_2(\theta^1)$ and expanding the first term, we get,

\[
\int_{\theta_s^1}^{\theta_s^2} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^1)\right), \theta, b\right) dF + \int_{\theta_s^2}^{\theta^2} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^1)\right), \theta, b\right) dF
\]

Comparing the above expression with the first two terms of $W^{RES}_2(\theta^2)$,

\[
\int_{\theta^1}^{\theta^2} U\left(\phi^2\left(x_2^* (\theta), x_1^* (\theta)\right), \theta, b\right) dF + \int_{\theta^2}^{\theta^2} U\left(\phi^2\left(x_2^* (\theta, \bar{m}^2), x_1^* (\bar{m}^2)\right), \theta, b\right) dF >
\]

\[
\int_{\theta_s^1}^{\theta^2} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^1)\right), \theta, b\right) dF + \int_{\theta^2}^{\theta^2} U\left(\phi^2\left(\bar{k}, x_1^* (\bar{m}^1)\right), \theta, b\right) dF
\]
This follows from pair-wise comparison of the terms,

\[
\int_{\theta_1^2}^{\theta_2^2} U \left( \phi^2 (x_2^*(\theta), x_1^*(\theta)) , \theta, b \right) dF > \int_{\theta_1^2}^{\theta_2^2} U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^1)) , \theta, b \right) dF \tag{9}
\]

\[
\int_{\theta_2^2}^{\bar{\theta}} U \left( \phi^2 (x_2^*(\theta), x_1^*(\bar{m}^2)) , \theta, b \right) dF > \int_{\theta_2^2}^{\bar{\theta}} U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^1)) , \theta, b \right) dF \tag{10}
\]

Similarly comparing the last term of \(W_2^{RES}(\theta^1)\) and \(W_2^{RES}(\theta^2)\),

\[
\int_{\bar{\theta}}^{\bar{\theta}} U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^2)) , \theta, b \right) dF > \int_{\bar{\theta}}^{\bar{\theta}} U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^1)) , \theta, b \right) dF \tag{11}
\]

The inequality 9 follows from noting that on the interval \((\theta_1^2, \theta_2^2]\), \(A_2\) achieves \(\bar{\theta}^2\) under the higher threshold equilibrium.

\[
\forall t \in (\theta_1^2, \theta_2^2] : U \left( \phi^2 (x_2^*(\theta), x_1^*(\theta)) , \theta, b \right) > U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^1)) , \theta, b \right)
\]

Similarly, inequality 10 is true since on the interval \((\theta_2, \theta_2^2]\), \(A_2\) induces \(A_1\) to allocate more with message \(\bar{m}^2\) and correspondingly changes its action to achieve first best \(\bar{\theta}^2\).

\[
\forall \theta \in (\theta_2, \theta_2^2] : U \left( \phi^2 (x_2^*(\theta), x_1^*(\bar{m}^2)) , \theta, b \right) > U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^1)) , \theta, b \right)
\]

The last inequality 11 follows from noting that since \(x_1^*(\bar{m}^1) < x_1^*(\bar{m}^2)\), it is valid that \(\phi^2 (\bar{k}, x_1^*(\bar{m}^1)) < \phi^2 (\bar{k}, x_1^*(\bar{m}^2))\) and because there is a positive spillover at the bound for \(A_2\), i.e. \(U_1 |_{\theta \in (\theta_2^2, \bar{\theta})} > 0\),

\[
\forall \theta \in (\theta_2^2, \bar{\theta}] : U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^2)) , \theta, b \right) > U \left( \phi^2 (\bar{k}, x_1^*(\bar{m}^1)) , \theta, b \right)
\]

Comparing the terms pairwise therefore yields the required result, \(W_2^{RES}(\theta^2) > W_2^{RES}(\theta^1)\).
**Scenario (b):** When $\theta_{s}^{1} > \theta_{s}^{2}$. That is, $\theta^{1} < \theta^{2} < \theta_{s}^{1} < \theta_{s}^{2}$.

In this case, as earlier, I will look at states in which there is inefficiency generated by information pooling and compare the residual welfare.

\[ W_{2}^{\text{RES}}(\theta^{1}) = \int_{\theta_{s}^{1}}^{\theta_{s}^{2}} U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{1})), \theta, b\right) \, dF + \int_{\theta_{s}^{2}}^{\theta} U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{1})), \theta, b\right) \, dF \]

\[ W_{2}^{\text{RES}}(\theta^{2}) = \int_{\theta_{s}^{1}}^{\theta_{s}^{2}} U\left(\phi^{2}(x^{*}_{2}(\theta, \bar{m}^{2}), x^{*}_{1}(\bar{m}^{2})), \theta, b\right) \, dF + \int_{\theta_{s}^{2}}^{\tilde{\theta}} U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{2})), \theta, b\right) \, dF \]

Pairwise comparison yields,

\[ \int_{\theta_{s}^{1}}^{\theta_{s}^{2}} U\left(\phi^{2}(x^{*}_{2}(\theta, \bar{m}^{2}), x^{*}_{1}(\bar{m}^{2})), \theta, b\right) \, dF > \int_{\theta_{s}^{2}}^{\theta_{s}^{1}} U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{1})), \theta, b\right) \, dF \quad (12) \]

\[ \int_{\theta_{s}^{2}}^{\tilde{\theta}} U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{2})), \theta, b\right) \, dF > \int_{\theta_{s}^{2}}^{\theta_{s}^{1}} U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{1})), \theta, b\right) \, dF \quad (13) \]

The inequalities 12 and 13 follow from arguments made earlier. Specifically, on $[\theta_{s}^{1}, \theta_{s}^{2}]$ $A_{2}$ is able to achieve $\tilde{\varphi}_{\theta}^{2}$ with the cutoff equilibrium $\theta^{2}$ and is therefore strictly better off compared to the equilibrium threshold $\theta^{1}$. In the interval $[\theta_{s}^{2}, \tilde{\theta}]$, there is inefficiency from miscoordination in that $\phi^{2}(.) < \phi_{\theta}^{2}$. However, since $A_{2}$ induces a higher action from $A_{1}$ under $\theta^{2}$ equilibrium, $x^{*}_{1}(\bar{m}^{2}) > x^{*}_{1}(\bar{m}^{1})$, it follows that $\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{1})) < \phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{2})) < \phi_{\theta}^{2}$ and given $U_{1} > 0$ on this interval,

\[ \forall \theta \in (\theta_{s}^{2}, \tilde{\theta}] : U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{2})), \theta, b\right) > U\left(\phi^{2}(\bar{k}, x^{*}_{1}(\bar{m}^{1})), \theta, b\right) \]

Therefore, $W_{2}^{\text{RES}}(\theta^{2}) > W_{2}^{\text{RES}}(\theta^{1})$. This completes the proof.  

**QED**
A.7 Proof of Lemma 2

The key to proving this is to look at all pairs of actions \((x_1, x_2)\) that achieve the first best for \(A_2\), in order to satisfy its IC and NC constraints. Given Assumption 1 and Assumption 2, for any \(\theta \in \bar{m}_p\), there are different action pairs \((x_1, x_2)\) such that \(\phi^2(x_2, x_1) = \bar{\phi}^2_\theta\). I proceed by constructing the set of \(\phi^1\) that corresponds with all admissible pairs \((x_1, x_2)\) such that for any \(\theta\), \(\phi^2(x_2, x_1) = \bar{\phi}^2_\theta\). The following defines this admissible set:

\[
\forall \theta \in \bar{m}_p, (x_2, x_1) \in V : A_\theta = \left\{ \phi^1(x_1, x_2) : \phi^2(x_2, x_1) = \bar{\phi}^2_\theta \right\}
\]

I will impose further structure on the set \(A_\theta\) for the interval \(\bar{m}_p\). From continuity property of \(\phi^1(\cdot)\) and \(\phi^2(\cdot)\), the set \(A_\theta\) is compact. Further, let \(\sup A_\theta = \phi^1_{\sup}(\theta)\) and \(\inf A_\theta = \phi^1_{\inf}(\theta)\). Let \(x_{1}\inf(\theta)\) be such that \(\phi^2\left(\bar{k}, x_{1}\inf(\theta)\right) = \bar{\phi}^2_\theta\).

CLAIM. \(\forall \theta \in \bar{m}_p : \phi^1(x_{1}\inf(\theta), \bar{k}) = \phi^1_{\inf}(\theta)\)

Proof. Note that \(x_2\) varies from \(\bar{k}\) to \(\bar{k}\) and \(x_1\) is just the residual contribution that ensures \(\phi^2(\cdot) = \bar{\phi}^2_\theta\). Applying total differentiation to \(\phi^2\), we get the following:

\[
d\phi^2 = \frac{\partial \phi^2}{\partial x_2} dx_2 + \frac{\partial \phi^2}{\partial x_1} dx_1
\]

Since \(\phi^2(\cdot) = \bar{\phi}^2_\theta\), a constant in \(A_\theta\), \(d\phi^2 = 0\). Substituting this in the above equation and rearranging,

\[
\left| \frac{dx_1}{dx_2} \right| = \frac{\frac{\partial \phi^2}{\partial x_2}}{\frac{\partial \phi^2}{\partial x_1}} > 1
\]

Similarly,

\[
d\phi^1 = \frac{\partial \phi^1}{\partial x_2} dx_2 + \frac{\partial \phi^1}{\partial x_1} dx_1
\]

\[
\frac{d\phi^1}{dx_2} = \frac{\partial \phi^1}{\partial x_2} + \frac{\partial \phi^1}{\partial x_1} \frac{dx_1}{dx_2} = \frac{\partial \phi^1}{\partial x_2} - \left| \frac{dx_1}{dx_2} \right| \frac{\partial \phi^1}{\partial x_1}
\]

(14)
\[ \Rightarrow \frac{d\phi^1}{dx_2} < \left[ \frac{\partial \phi^1}{\partial x_1} - \left| \frac{dx_1}{dx_2} \right| \frac{\partial \phi^1}{\partial x_1} \right] = \frac{\partial \phi^1}{\partial x_2} \cdot \left| 1 - \left| \frac{dx_1}{dx_2} \right| \right| < 0 \] (15)

Equation 15 follows from imperfect substitutability in that \( \frac{\partial \phi^1}{\partial x_1} > \frac{\partial \phi^1}{\partial x_2} \). This further establishes that \( \phi^1 \) is decreasing in the actions of \( A_2 \). Therefore the infimum of the set \( A_\theta \) corresponds with the pair of actions in which \( A_2 \) takes the maximal action \( \bar{k} \) and \( A_1 \), the residual \( x_1^{inf}(\theta) \).

**CLAIM.** \( \forall \theta \in \bar{m}_p : \phi^1_{inf}(\theta) > \bar{\phi}_\theta^1 \)

**Proof.** From lemma 4 it is clear there is an ordering over \( \phi^1 \). Specifically, \( \phi^1_{sup}(\theta) > \ldots > \phi^1_{inf}(\theta) \). Suppose \( \phi^1_{inf}(\theta) > \bar{\phi}^1_\theta \) were not true. Then, either \( \phi^1_{sup}(\theta) > \ldots > \bar{\phi}^1_\theta > \ldots > \phi^1_{inf}(\theta) \) or \( \bar{\phi}^1_\theta > \phi^1_{sup}(\theta) > \ldots > \phi^1_{inf}(\theta) \). If the former was true, then \( A_2 \) can achieve first best by truthfully revealing the state \( \theta \). That is, \( A_2 \) could have revealed truthfully up to some higher threshold \( \bar{\theta} \), which violates the most informative threshold equilibrium \( \bar{\theta} \). The latter cannot be true because of the imperfect substitutability assumption and a positive conflict of interest. Therefore it must hold that \( \phi^1_{sup}(\theta) > \ldots > \phi^1_{inf}(\theta) > \bar{\phi}^1_\theta \).

From the above claims, it is clear that on the interval \( \bar{m}_p \), there is over-provision for agent \( A_1 \) as long as \( A_2 \) achieves first best. However, precisely for this reason, it implies that \( U_1 < 0 \) and therefore the following holds:

\[ \forall \theta \in \bar{m}_p : \phi^1_{inf}(\theta) = \arg\max_{\phi^1 \in A_\theta} U(\phi^1, \theta) \] (16)

That is, of all action pairs \( (x_1, x_2) \) that satisfy \( A_2 \)'s IC constraint for truth-telling, the one that maximizes \( A_1 \)'s utility is the one that minimizes this miscoordination from over-provision, which coincides with \( x_2^c = \bar{k} \). Suppose there was a strictly increasing interval \( (\theta_1, \theta_2) \in \bar{m}_p \) such that \( \exists \theta' \in (\theta_1, \theta_2) : x_2^c(\theta', x_1^c(\theta')) < \bar{k} \). Then, given that IC and NC must be satisfied, \( \phi^1(x_1^c(\theta'), x_2^c(\theta', x_1^c(\theta'))) \in A_1 \theta' \). But clearly from the earlier arguments, \( A_1 \) can always instead choose to take an action \( x_1^{inf}(\theta') \) such that
\[ x^c_2(\theta', x^{inf}_1(\theta')) = \bar{k}. \]

This satisfies IC of \( A_2 \) since \( \phi^1(x^{inf}_1(\theta'), \bar{k}) \in A_{\theta'} \) and increases the payoff to \( A_1 \) since

\[ U(\phi^1(x^{inf}_1(\theta'), \bar{k}, \theta')) > U(\phi^1(x^c_1(\theta'), x^c_2(\theta', x^c_1(\theta'))), \theta'). \]

### A.8 Proof of Proposition 3

To show the optimal commitment rule indeed takes the form described in Proposition 3, I will start by proving Claim 1- Claim 5.

#### A.8.1 Proof of Claim 1

Suppose the claim weren’t true and say \( A_1, \) wlog, allocates \( x^c_1(\theta) = z, \forall \theta \in \bar{m}_p. \) There are three possible cases to consider.

**Case i)** \( z = \bar{x}_1(\bar{\theta}) \equiv \bar{z} \)

In this case, \( A_2' \)s NC constraint dictates that \( x^c_2 = \bar{k} \) for every possible type in \( \bar{m}_p, \) since \( U_{12} > 0. \) If this is so, then \( \forall \theta \in \bar{m}_p \colon \phi^1(\bar{x}_1(\bar{\theta}), \bar{k}) = \bar{\phi}_\theta^1 < \bar{\phi}_\theta^1. \) This implies that the expected marginal utility of \( A_1 \) is greater than zero and given \( U_{11} < 0, \) there is an incentive for \( A_1 \) to increase her actions. Therefore, \( z \neq \bar{x}_1(\bar{\theta}). \)

**Case ii)** \( z = \bar{z} \equiv \arg\max_{x_1 \in V} U(\phi^2(\bar{k}, x_1), \bar{\theta}, b) \)

This corresponds with the case where \( A_1 \) provides first best joint coordination levels to \( A_2 \) for all \( \theta \in \bar{m}_p, \) i.e. \( x^c_2(\bar{\theta}, \bar{z}) = \bar{k} \) and,

\[ \forall \theta \in (\bar{\theta}, \bar{\theta}) : x^c_2(\theta, \bar{z}) < \bar{k} \]

Let \( \bar{z} = \bar{x}_1(\bar{\theta}) + \Delta_1(\bar{\theta}) \) and \( x^c_2(\theta, \bar{z}) = \bar{k} - \Delta_2(\theta) \) such that \( \Delta_2(\bar{\theta}) = 0 \) on the interval \( \bar{m}_p. \) Then, due to Assumption 3 it must be that the difference \( \phi^2(\bar{k}, \bar{z}) - \bar{\phi}_\theta^2 > \)

67
\( \phi^1(z, k) - \phi^1_\theta \). This follows from noting that \( \phi^2(k, z) = \phi^2_\theta \) by definition and since there is imperfect substitutability it follows that keeping \( x_2 \) fixed, \( d\phi^1 = \frac{\partial \phi^1}{\partial x_1} dx_1 > d\phi^2 \) implying that \( \phi^1(z, k) > \phi^1_\theta \). Since \( x^c_2(\theta, z) < \bar{k} \) and \( \phi^2(\cdot) = \phi^2_\theta \) on the interval \( \bar{m}_p \), it must be from continuity of the coordination functions that the sequence \( (\phi^1(\bar{x}_1(\bar{\theta}) + \bar{\Lambda}_1(\bar{\theta}), \bar{k} - \bar{\Lambda}_2(\theta)) - \phi^1_\theta)^n \rightarrow \bar{c} > 0 \) i.e. the sequence is pointwise bounded away from zero. Therefore there is over-provision over the entire interval \( \bar{m}_p \) and the marginal utility for \( A_1 \) is decreasing at \( \bar{z} \).

**Case ii):** \( z \equiv \bar{z} \in (\bar{z}, \bar{z}) \)

If this were true, then the following inequalities hold.

\[
\begin{align*}
x^c_2(\bar{\theta}, \bar{z}) &= \bar{k} \\
x^c_2(\bar{\theta}, \bar{z}) &< \bar{k}
\end{align*}
\]

The first follows directly from NC constraint and the second holds since \( \phi^2(\bar{k}, \bar{z}) > \phi^2(\bar{k}, \bar{z}) = \phi^2_\theta \). But if this were true, then there exists some types such that \( A_2 \) allocates less than \( \bar{k} \) and still achieves first best. That is,

\[
\exists \theta' \in (\bar{\theta}, \bar{\theta}) \text{ such that } x^c_2(\theta, \bar{z}) \equiv \arg\max_{\theta \in V} U \left( x^2_2(z), \theta, b \right) < \bar{k} \text{ for all } \theta \in (\bar{\theta}, \bar{\theta})
\]

From the continuity property of \( U(\cdot) \) and \( \phi^j(\cdot) \), when \( z > x^c_1(\bar{\theta}) \), then there is always a cutoff type \( \theta' \) such that \( x^c_2(\theta', z) = \bar{k} \). However, this implies that for all types in the interval \( (\bar{\theta}, \theta') \) it must be that \( x^c_2(\theta, z) < \bar{k} \). If this set exists, then \( A_1 \) is not maximizing its expected utility since it can always reduce actions and make \( A_2 \) contribute \( \bar{k} \), due to Lemma 2. To see this, consider the following alternate action rule:
∀t ∈ (\bar{\theta}, \theta') : x^e_1(t) = x^{ inf}_1(t) \text{ such that } \phi^1(x^{ inf}_1(t), k) = \phi^1_{inf}(t) ∈ A_t

∀t' ∈ \bar{m}_p \setminus (\bar{\theta}, \theta') : x^e_1(t') = z

Clearly, on the interval subset (\bar{\theta}, \theta'), A_1 now achieves a greater expected utility since ∀t ∈ (\bar{\theta}, \theta') : U_1(\phi^1(x^{ inf}_1(t), k), t) > U_1(\phi^1(z, x^c_1(t,z)), t). Further, this action rule is also incentive compatible in that A_2 cannot do better by misreporting. Therefore, there cannot be a single flat segment on \bar{m}_p. This proves Claim 1.

A.8.2 Proof of Claim 2

Consider, wlog, two pooling intervals (\theta_1, \theta'_1) and (\theta_2, \theta'_2) such that \theta_1 < \theta'_1 < \theta_2 < \theta'_2. Suppose z_1 and z_2 are the two pooling actions associated with the pooling segments respectively. From Lemma 2 and Claim 1 the following is statements hold:

∀θ ∈ (t_i, \theta'_i) : x^c_2(θ, z_i) = \bar{k}, \quad i ∈ \{1, 2\}

Pick a \theta''_1 = \theta_1 + \epsilon_1 ∈ (\theta_1, \theta'_1). Clearly, \phi^2(x^c_2(\theta''_1, z_1), z_1) < \phi^2_{\theta''_1}.

As a result, \( U_1(\phi^2(x^c_2(\theta''_1, z_1), z_1), \theta''_2, b) > 0 \). If \theta''_1 reports to be in the higher pooling segment (\theta_2, \theta'_2), then the deviation action \( x^d_2(\theta''_1, z_2) \) is such that,

\[ x^d_2(\theta''_1, z_2) = \arg\max_{x_2 \in V} U(\phi^2(x^c_2(\theta''_1, z_2), \theta''_2, b)) \]

If \( x^d_2(.) < \bar{k} \) then \( \phi^2(.) = \phi^2_{\theta''_1} \) and the deviation is clearly better for A_2, thereby violating the NC and IC constraints. If \( x^d_2(.) = \bar{k} \) on the other hand, then,

\[ \phi^2_{\theta''_1} ≥ \phi^2(x^c_2(\theta''_1, z_2), z_2) > \phi^2(x^c_2(\theta'_1, z_1), z_1) \]

\[ \implies U_1(\phi^2(x^c_2(\theta''_1, z_2), \theta''_2, b)) > U_1(\phi^2(x^c_2(\theta'_1, z_1), \theta''_2, b)) \]
This completes the proof of Claim 2.

A.8.3 Proof of Claim 3

Suppose, instead there exists a flat segment followed by a strictly increasing segment in $\bar{m}_p$. Say, wlog, the flat segment is on $(\theta_1, \theta'_1]$ such that $\forall t \in (\theta_1, \theta'_1] : x^c_1(t) = z$, and let the strictly increasing segment be on $(\theta_2, \theta'_2)$. From Lemma 2, it holds that $A_2$ must take an action $\bar{k}$ and the IC constraint must be satisfied on the separating interval in that $\forall t \in (\theta_2, \theta'_2) : \phi^2(\bar{k}, x^\text{inf}_1(t)) = \phi^2_\bar{k}$. Similarly from Claims 1-2 it must be that for all $t \in (\theta_1, \theta'_1)$:

$$x^c_2(t, z) \equiv \arg\max_{x_2 \in V} U (\phi^2(x_2, z), t, b) = \bar{k}$$

$$\phi^2(\bar{k}, z) < \phi^2_\bar{k}$$

This however implies that the pooling action is always lower than the separating region actions, i.e. $z < x^\text{inf}_1(t)$ for all $t \in (\theta_2, \theta'_2)$. Take any type $t \in (\theta_1, \theta'_1)$. For this type it must be that by deviating and reporting to be a higher type in $(\theta_2, \theta'_2)$ would increase its expected payoff. To see this, let us again consider the deviation action if $t \in (\theta_1, \theta'_1)$ reports to be $t' \in (\theta_2, \theta'_2)$. The deviation action for $A_2$ type $t$ is,

$$x^d_2(t, x^\text{inf}_1(t')) \equiv \arg\max_{x_2 \in V} U (\phi^2(x_2, x^\text{inf}_1(t')), t, b)$$

As before, if $x^d_2(.) < \bar{k}$, then it implies $\phi^2(x^d_2(.), x^\text{inf}_1(t')) = \phi^2_\bar{k}$ and $A_2$ has an incentive to exaggerate and claim to be a higher type in the separating region. On the other hand, if $x^d_2(.) = \bar{k}$ then since $z < x^\text{inf}_1(t')$ and $\phi^2_\bar{k} < \phi^2_{t'}$,

$$\phi^2(\bar{k}, z) < \phi^2(\bar{k}, x^\text{inf}_1(t')) \leq \phi^2_{t'}$$

$$\implies U (\phi^2(\bar{k}, x^\text{inf}_1(t')), t, b) > U (\phi^2(\bar{k}, z), t, b)$$

The above violates IC constraint of the types in the pooling region. Therefore there can never be a separating region following a pooling region on $\bar{m}_p$. This proves Claim 3.
A.8.4 Proof of Claim 4

The claim directly follows from Claim 3. That is, if there exists two separating intervals on $\bar{m}_p$, then it cannot be that there is a pooling region in between the two separating intervals. If there are two adjacent intervals $(\theta_1, \theta_1')$ and $(\theta_1', \theta_2)$ such that there is a discontinuous jump in $A_1$’s action at $\theta_1'$, then say $x^L_1(\theta_1')$ and $x^H_1(\theta_1')$ are such that $x^L_1(\theta_1') < x^H_1(\theta_1')$. It immediately implies that $x^L_1(\theta_1')$ is the infimum of $x^H_1(\theta_1')$ and the higher separating action $x^H_1(\theta_1')$ must therefore induce an action less than $\bar{k}$ from $A_2$, i.e.,

$$x^H_1(\theta_1') \equiv \arg\max_{x_2 \in V} U\left(\phi^2(x_2, x^H_1(\theta_1'), \theta_1', b)\right) < \bar{k}$$

This cannot be optimal for $A_1$ since this action does not minimize the miscoordination (refer to Lemma 2). This proves Claim 4.

A.8.5 Proof of Claim 5

Claim 1-Claim 4 imply that the optimal commitment problem can be reformulated as the following on the pooling interval,

$$W^c_1 = \arg\max_{x_1(\theta) \in V} \int_\theta^t U\left(\phi^1(x_1(\theta), \bar{k}), \theta\right) dF + \int_t^\theta U\left(\phi^1(x_1(t), \bar{k}), \theta\right) dF$$

such that

$$x_1^c(\theta) \equiv \arg\max_{x_1 \in V} U\left(\phi^2(\bar{k}, x_1), \theta, b\right), \quad \phi^2(\bar{k}, x_1^c(t)) = \bar{\phi}_t^2$$

The reformulation basically reduces the commitment problem to an optimal control problem with a modified IC constraint such that there is a cutoff state $t$ up to which $A_2$ gets first best. Correspondingly, $t$ is the state variable and $x_1^c(\theta)$ is the control variable. Given that the utility function and the coordination function are twice continuously differentiable in $x_1$, the above problem is equivalent to choosing an optimal cutoff $t$. The
first order condition is given by,

\[
\frac{dW^c_1}{dt} = \int_t^{\tilde{\theta}} U_1 \left( \phi^1 \left( x^c_1(t), \bar{k} \right), \theta \right) \cdot \left[ \frac{d\phi^1 \left( x^c_1(t), \bar{k} \right)}{dx_1} \cdot x^c_1(t) \right] dF = 0 \tag{17}
\]

The term \[U \left( \phi^1 \left( x^c_1(t), \bar{k} \right), \theta \right) - U \left( \phi^1 \left( x^c_1(t), \bar{k} \right), \theta \right)\] \(f(t) = 0\) and therefore not been included in the FOC above. Since \[\left[ \frac{d\phi^1 \left( x^c_1(t), \bar{k} \right)}{dx_1} \cdot x^c_1(t) \right] > 0,\]

\[
\left. \frac{dW^c_1}{dt} \right|_{t \uparrow \tilde{\theta}} = U_1 \left( \phi^1 \left( x^c_1(\tilde{\theta}), \bar{k} \right), \tilde{\theta} \right) \cdot \left[ \left. \frac{d\phi^1 \left( x^c_1(t), \bar{k} \right)}{dx_1} \right|_{t \uparrow \tilde{\theta}} \cdot x^c_1(\tilde{\theta}) \right] f(\tilde{\theta}) < 0
\]

This directly follows from noting that \(x^c_1(\tilde{\theta}) \equiv \arg\max_{x_1 \in V} U \left( \phi^2(\bar{k}, x_1), \tilde{\theta}, b \right)\) which implies from previous arguments (Lemma 2) that \(\phi^1 \left( x^c_1(\tilde{\theta}), \bar{k} \right) > \tilde{\phi}^1_0\). Therefore \(U_1 < 0\) and this concludes the proof of Claim 5.

Together, the five claims imply the following rules hold under the optimal commitment mechanism:

1. On the interval \([0, \bar{\theta}]\), the optimal ex ante action rule mimics the simultaneous protocol actions, \(\bar{x}_1(\theta)\).

2. There is a cutoff \(\bar{\theta}_c \in m_{pool}\) such that \(A_1\)’s action rule is dependent on communication up to \(\bar{\theta}_c\) and given by \(x^c_1(\theta) = x^{inf}_1(\theta)\); \(A_2\)’s action is \(x^c_2(\theta) = \bar{k}\) such that \(\phi^2(\bar{k}, x^{inf}_1(\theta)) = \tilde{\phi}^2_0\) and \(\phi^1(x^{inf}_1(\theta), \bar{k}) \in \mathcal{A}_\theta\).

3. Finally, Claim 5 \(\implies\) \(\bar{\theta}_c < \tilde{\theta}\) and on the interval \([\bar{\theta}_c, \tilde{\theta}]\), \(A_1\)’s action is independent of communication and is equal to \(x^c_1(\theta) = x^c_1(\bar{\theta}_c)\).

This completes the proof. QED
A.9 Proof of Proposition 4

Under simultaneous actions with no commitment, the agent $A_1$ plays an expected action $x_1^s(\bar{m}_p) \equiv x_1^{\bar{m}_p}$ on the pooling interval $\bar{m}_p$. In response, the agent $A_2$ plays $x_2^s(\theta, \bar{m}_p)$ for every possible type. Subsection A.4 provides the solution to $A_1$’s problem of choosing $x_1^s$ and can be rewritten for the most informative equilibrium ex ante as the solution of the following FOC,

$$
\int_{\bar{\theta}_s}^{\theta} U_1 \left( \phi_1^1(x_1^s, x_2^s(\theta, \bar{m}_p)), \theta \right) \cdot \frac{d\phi_1^1}{dx_1} \bigg|_{x_1=x_1^{\bar{m}_p}} dF + \int_{\bar{\theta}_s}^{\theta} U_1 \left( \phi_1^1(x_1^s, k), \theta \right) \cdot \frac{d\phi_1^1}{dx_1} \bigg|_{x_1=x_1^{\bar{m}_p}} dF = 0 \quad (18)
$$

At $\bar{\theta}_s$, it follows that $\phi_2^2(\bar{k}, x_1^{\bar{m}_p}) = \phi_2^2(\bar{\theta}_s)$. $A_2$ therefore achieves first best levels of coordination on the interval $(\bar{\theta}, \bar{\theta}_s]$. Consider the following commitment protocol sequence of actions for $A_1$ on $\bar{m}_p$:

$$
\forall \theta \in (\bar{\theta}, \bar{\theta}_s) : x_1^c(\theta) = x_1^{\inf}(\theta)
$$

$$
\forall \theta \in [\bar{\theta}_s, \bar{\theta}] : x_1^c(\theta) = x_1^s(\bar{m}_p) \equiv x_1^{\bar{m}_p}
$$

The above commitment rule replicates the simultaneous protocol cutoff $\bar{\theta}_s$ in that it provides $A_2$ first best joint coordination $\phi_2^2(\theta)$ on the interval $(\bar{\theta}, \bar{\theta}_s]$. Clearly, this action rule is IC for $A_2$ and provides the same expected ex ante welfare to $A_2$ compared to simultaneous protocol case. $A_1$’s expected welfare is equal to that of simultaneous protocol only on the interval $[\bar{\theta}_s, \bar{\theta}]$. However, $\forall t \in (\bar{\theta}, \bar{\theta}_s)$, $A_1$ actually does better since $A_2$’s action is maximal ($\bar{k}$) on this interval and this minimizes the inefficiency from miscoordination. That is,

$$
\forall \theta \in (\bar{\theta}, \bar{\theta}_s) : U_1 \left( \phi_1^1 \left( x_1^{\inf}(\theta), \bar{k} \right), \theta \right) > U_1 \left( \phi_1^1 \left( x_1^s(\theta, \bar{m}_p) \right), \theta \right)
$$

Therefore by following an IC commitment rule that is strictly increasing on $(\bar{\theta}, \bar{\theta}_s)$ and flat on $[\bar{\theta}_s, \bar{\theta}]$, $A_1$ achieves a higher ex ante welfare while $A_2$ is indifferent compared to the case of simultaneous decision making. Now consider the sequence of actions
that,

The above inequality follows from multiplying Equation 21 throughout by the term

\[ \left\{ x_1^{\text{inf}}(\theta) \right\}_{\theta \in (\bar{\theta}, \tilde{\theta})} \]  

and checking the marginal utility of \( A_1 \) for each type in the interval,

\[
U_1 \left( \phi^1 \left( x_1^s, x_2^s(\theta, \bar{m}_p) \right), \theta \right) < U_1 \left( \phi^1 \left( x_1^{\text{inf}}(\theta), \bar{k} \right), \theta \right)
\]  

(19)

Equation 19 follows from noting that utility of \( A_1 \) is decreasing in \( \phi^1 \) on this interval and since \( U_{11} < 0 \) and \( \phi^1 \left( x_1^s, x_2^s(\theta, \bar{m}_p) \right) > \phi^1 \left( x_1^{\text{inf}}(\theta), \bar{k} \right) = \phi^1_{\text{inf}}(\theta) > \bar{\phi}^1_\theta \). Now, on the interval \([\bar{\theta}, \tilde{\theta}]\), since \( x_1^c(\theta) = x_1^s \), the ex ante commitment rule provides the same expected marginal utility as simultaneous protocol for \( A_1 \). Rewriting Equation 18 with the sequence \( \left\{ x_1^{\text{inf}}(\theta) \right\}_{\theta \in (\bar{\theta}, \tilde{\theta})} \) and \( \left\{ x_1^c \right\}_{\theta \in [\bar{\theta}, \tilde{\theta}]} \), it is clear that,

\[
\int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^{\text{inf}}(\theta), \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^{\text{inf}}} d\theta + \int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^s, \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^s} d\theta > 0
\]  

(20)

\[
\int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^s, \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^s} d\theta > -\int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^{\text{inf}}(\theta), \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^{\text{inf}}} d\theta > 0
\]  

(21)

From Equation 17, it is immediately clear that evaluating the equation at \( t = \bar{\theta} \) and substituting \( x_1^c(\bar{\theta}) = x_1^s \) gives,

\[
\int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^c, \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^c} x_1^c(\bar{\theta})d\theta > -\int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^{\text{inf}}(\theta), \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^{\text{inf}}} x_1^c(\bar{\theta})d\theta
\]  

(22)

The above inequality follows from multiplying Equation 21 throughout by the term \( x_1^c(\bar{\theta}) \). Since \( U_1 \left( \phi^1 \left( x_1^{\text{inf}}(\theta), \bar{k} \right), \theta \right) < 0 \) everywhere on the interval \( (\bar{\theta}, \tilde{\theta}) \), it follows that,

\[
\int_{\bar{\theta}}^{\tilde{\theta}} U_1 \left( \phi^1 \left( x_1^s, \bar{k} \right), \theta \right) \frac{d\phi^1}{dx_1} \bigg|_{x_1=x_1^s} x_1^c(\bar{\theta})d\theta > 0
\]  

74
Therefore, the expected marginal utility of $A_1$ from choosing the cutoff $\bar{\theta}_s$ is increasing and this implies that $\bar{\theta}_c > \bar{\theta}_s$. Further, $x_1^c(\bar{\theta}_c) > x_1^s$.

$A_1$’s welfare

By replacing the commitment protocol actions in the FOC of the simultaneous protocol (Equation 18), we get back Equation 20 which states that the commitment rule guarantees at least as much expected utility as the no commitment case since the marginal utility is increasing at the cutoff $\bar{\theta}_s$. Therefore, the expected utility from the commitment rule is greater compared to simultaneous protocol for $A_1$.

$A_2$’s welfare

On the interval $[0, \bar{\theta}_c]$, $A_2$ achieves first best levels of joint coordination in that $\forall t \in [0, \bar{\theta}_c] : \phi^2(.,) = \bar{\phi}_t^2$ under the optimal commitment rule. For all $t \in (\bar{\theta}_c, 1]$, $x_1^c(\bar{\theta}_c) > x_1^s$ and $x_1^c(\bar{\theta}_s) = x_1^s$ which implies $\bar{\phi}_t^2 > \phi^2(\bar{k}, x_1^c(\bar{\theta}_c)) > \phi^2(\bar{k}, x_1^s)$. Since there is under-provision (miscoordination) for $A_2$ on this interval,

$$\int_{\bar{\theta}_c}^{\bar{\theta}} U(\phi^2(\bar{k}, x_1^c(\bar{\theta}_c)), \theta, b) \, dF > \int_{\bar{\theta}_c}^{\bar{\theta}} U(\phi^2(\bar{k}, x_1^s), \theta, b) \, dF$$

The above inequality follows from noting that $U(\phi^2(\bar{k}, x_1^c(\bar{\theta}_c)), \theta, b) > U(\phi^2(\bar{k}, x_1^s), \theta, b)$ everywhere on the interval. Therefore, the overall expected ex ante welfare is greater under the optimal commitment mechanism. This completes the proof. QED
B Proofs - Uniform Quadratic Example

B.1 Proof of Proposition 5

(a) To ensure partial information revelation, but not full or no informative communication, the following boundary conditions for truth-telling have to be satisfied. Specifically, it is straightforward to observe that when the state is known then
\[ \bar{x}_1(\theta) = \theta - \frac{\eta}{1-\eta} b \] and \[ \bar{x}_2(\theta) = \theta + \frac{1}{1-\eta} b. \] This implies that the boundary actions for the agents are,
\[ (\bar{x}_1(0), \bar{x}_2(0)) = (0, (1 + \eta)b) \]
\[ (\bar{x}_1(1), \bar{x}_2(1)) = \left(1 - \frac{\eta}{1-\eta} b, 1 + \frac{1}{1-\eta} b\right) \]
Therefore for partial information revelation, \( \bar{k} > (1 + \eta)b, \bar{k} < 1 + \frac{1}{1-\eta} b, \) and \( (1 + \eta)b < 1 + \frac{1}{1-\eta} b. \) This proves the first part of the proposition.

(b) Under the simultaneous protocol, the action of agent \( A_1 \) given the pooling message \( \bar{m}_p, x^s_1(\bar{m}_p), \) can be computed from the following equality,
\[ \frac{\bar{k} + \eta x_1}{1 + \eta} = (\bar{\theta}_s + b) \]
The above equation states that there exists a state \( \bar{\theta}_s \in \bar{m}_p \) and an action of \( A_1, x^s_1, \) such that the informed agent’s action is exactly equal to \( \bar{k} \) (follows from subsection A.4 and the associated lemma). Rewriting the above gives,
\[ x_1 = \frac{1 + \eta}{\eta} (\bar{\theta}_s + b) - \frac{1}{\eta} \bar{k} \] (23)
For \( A_2 \) the actions are best responses to \( x_1 \) in equilibrium,
\[ \forall \theta \in (\bar{\theta}, \bar{\theta}_s): x^s_2(\theta, \bar{m}_p) = (1 + \eta)(\theta + b) - \eta x_1 \]
Substituting for $x_1^s(m_p)$ from Equation 23 and simplifying yields,

$$x_2^s(\theta, m_p) = \bar{k} - (1 + \eta)(\bar{\theta}_s - \bar{\theta})$$  \hspace{1cm} (24)

Clearly, when $\bar{\theta} > \bar{\theta}_s$, the agent’s action is bounded by $\bar{k}$. This characterizes $A_2$’s actions on the pooling interval. To solve for $x_1^s(m_p)$, I use subsection A.4. The maximization problem for the agent $A_1$ on the pooling interval can be stated as,

$$x_1^s(m_p) \equiv \arg\max_{x_1 \in [0, \bar{k}]} \int_{\bar{\theta}_s}^{\bar{\theta}} \left( \frac{x_1 + \eta x_2^s(\theta, m_p)}{1 + \eta} - \theta \right)^2 f(\theta) d\theta - \int_{\bar{\theta}_s}^{1} \left( \frac{x_1 + \eta \bar{k}}{1 + \eta} - \theta \right)^2 f(\theta) d\theta$$  \hspace{1cm} (25)

The FOC yields,

$$-\int_{\bar{\theta}_s}^{\bar{\theta}} \left( \frac{x_1 + \eta x_2^s(\theta, m_p) - \theta}{1 + \eta} \right) f(\theta) d\theta = 0$$

Using equations 23 and 24, and rewriting the terms in the integral,

$$\frac{x_1 + \eta x_2^s(\theta, m_p)}{1 + \eta} = \frac{1}{\eta}(\bar{\theta}_s + b) - \frac{1 - \eta}{\eta} \bar{k} - \eta(\bar{\theta}_s - \bar{\theta})$$

$$\frac{x_1 + \eta \bar{k}}{1 + \eta} = \frac{1}{\eta}(\bar{\theta}_s + b) - \frac{1 - \eta}{\eta} \bar{k}$$

Substituting them back into the FOC,

$$\int_{\bar{\theta}_s}^{\bar{\theta}} \left[ (1 - \eta^2)\bar{\theta}_s - (1 - \eta)\bar{k} + b - \eta(1 - \eta)\theta \right] f(\theta) d\theta + \int_{\bar{\theta}_s}^{1} \left[ \bar{\theta}_s - (1 - \eta)\bar{k} + b - \eta\theta \right] f(\theta) d\theta = 0$$

Applying the fact that the pdf of an uniform distribution over any interval $(a, b)$ is
given by \( f(\theta) = \frac{1}{b-a} \), and solving the above equation for \( \bar{\theta}_s \) gives:

\[
\left[ 2 - \eta - \frac{\eta^2}{2} \right] \bar{\theta}_s = \frac{(4 + \eta)(1 - \eta)}{2} \bar{k} - \frac{(4 + \eta)}{2} b + \frac{\eta}{2}
\]

Simplifying the above gives,

\[
\bar{\theta}_s = \frac{(4 + \eta)(1 - \eta)}{(4 + \eta)(1 - \eta) + \eta} \bar{k} - \frac{(4 + \eta)}{(4 + \eta)(1 - \eta) + \eta} b + \frac{\eta}{(4 + \eta)(1 - \eta) + \eta}
\]

Substituting this back into Equation 23 and simplifying gives,

\[
x^s_1(\bar{m}_p) = \frac{1 + \eta}{\eta} \left[ \frac{(4 + \eta)(1 - \eta)}{(4 + \eta)(1 - \eta) + \eta} \bar{k} - \frac{\eta(3 + \eta)}{(4 + \eta)(1 - \eta) + \eta} b + \frac{\eta}{(4 + \eta)(1 - \eta) + \eta} \right] - \frac{1}{\eta} \bar{k}
\]

\[\Rightarrow x^s_1(\bar{m}_p) = \frac{(4 + \eta)(1 - \eta) - 1}{(4 + \eta)(1 - \eta) + \eta} \bar{k} - \frac{(3 + \eta)(1 + \eta)}{(4 + \eta)(1 - \eta) + \eta} b + \frac{(1 + \eta)}{(4 + \eta)(1 - \eta) + \eta}
\]

Together the set of actions \( (x^s_1, x^s_2(\theta, \bar{m}_p))_{\theta \in \bar{m}_p} \) completely describe the profile of actions for the agents when information is pooled under no commitment.

(c) With commitment, \( A_2 \)'s action is always \( \bar{k} \) on the pooling interval. \( A_1 \) chooses instead a cutoff \( \bar{\theta}_c \) and a stream of actions \( x^c_1(\theta) \) for all \( \theta \in (\bar{\theta}_s, \bar{\theta}_c) \) on \( \bar{m}_p \). The stream of actions can be computed from the following,

\[
\frac{\bar{k} + \eta x^c_1(\theta)}{1 + \eta} = \theta + b
\]

\[\Rightarrow x^c_1(\theta) = \frac{1 + \eta}{\eta} (\theta + b) - \frac{1}{\eta} \bar{k}
\]

Proposition 3 characterizes the optimal cutoff choice problem for \( A_1 \). Rewriting the
equation in Proposition 3 for the parameterized case,

\[ \bar{\theta}_c \equiv \arg\max_{t \in m_p} - \int_{\bar{\theta}}^{t} \left( \frac{1+\eta(t+b) - \frac{1-\eta^2}{\eta} \tilde{k}}{1+\eta} - \theta \right)^2 f(\theta) d\theta - \int_{t}^{1} \left( \frac{1+\eta(t+b) - \frac{1-\eta^2}{\eta} \tilde{k}}{1+\eta} - \theta \right)^2 f(\theta) d\theta \]

(26)

To find the solution to the above equation, I can focus attention only to the second integral in the FOC. (The terms that differentiate the limits vanish in the FOC.)

\[ \int_{t}^{1} \left( \frac{1}{\eta} (t+b - (1-\eta)\tilde{k}) - \theta \right) f(\theta) d\theta = 0 \]

\[ \frac{1}{\eta} (t+b - (1-\eta)\tilde{k}) - \frac{1+t}{2} = 0 \]

Simplifying this equation gives the required expression for \( \bar{\theta}_c \).

\[ \bar{\theta}_c = \frac{2(1-\eta)}{(2-\eta)} \tilde{k} - \frac{2}{(2-\eta)} b + \frac{\eta}{(2-\eta)} \]

(d) Subtracting the two thresholds yields,

\[ \bar{\theta}_d = \frac{\eta(2+\eta)}{8-8\eta+\eta^3} b - \frac{\eta(1-\eta)(2+\eta)}{8-8\eta+\eta^3} \tilde{k} + \frac{\eta(1-\eta)(2+\eta)}{8-8\eta+\eta^3} \]

Simplifying and collecting terms,

\[ \bar{\theta}_d = \frac{\eta(2+\eta)}{8-8\eta+\eta^3} [b + (1-\eta)(1-\tilde{k})] \]

Clearly \( \bar{\theta}_d > 0 \) as long as \( \tilde{k} < 1 + \frac{1}{1-\eta} b \), which is a sufficient condition for a PRTE to exist. This completes the proof. \( \text{QED} \)
B.2 Proof of Proposition 6

\(A_2\)'s Welfare:

\(A_2\) achieves first best on the interval \([0, \bar{\theta}_s]\) under the simultaneous protocol and on \([0, \bar{\theta}_c]\) with commitment. As a result the welfare calculation is straightforward. Since \(\bar{\phi}_{\bar{\theta}_s} = \bar{\theta}_s + b\), in the simultaneous protocol,

\[
W_s^2 = -\int_{\bar{\theta}_s}^{1} (\bar{\theta}_s - \theta)^2 f(\theta) d\theta
\]

Very simple algebra yields,

\[
W_s^2 = \frac{2}{3} \bar{\theta}_s - \frac{1}{3} \bar{\theta}_s^2 - \frac{1}{3}
\]

Substituting for \(\bar{\theta}_s\) and simplifying,\(^{35}\)

\[
W_s^2 = -\frac{1}{3} \frac{(4 + \eta)^2(1 - \eta)^2}{(4 - 2\eta - \eta^2)^2} \left( 1 - \bar{k} + \frac{b}{(1 - \eta)} \right)^2
\]

Similarly, with commitment \(\bar{\phi}_{\bar{\theta}_c} = \bar{\theta}_c + b\) and therefore,

\[
W_c^2 = \frac{2}{3} \bar{\theta}_c - \frac{1}{3} \bar{\theta}_c^2 - \frac{1}{3}
\]

\[
W_c^2 = -\frac{4}{3} \frac{(1 - \eta)^2}{(2 - \eta)^2} \left( 1 - \bar{k} + \frac{b}{(1 - \eta)} \right)^2
\]

The welfare gains (value) of commitment for \(A_2\) is just the difference between the two payoffs,

\[
G^2 = W_c^2 - W_s^2 = \frac{1}{3} \frac{\eta(\eta + 2)(1 - \eta)^2(16 - 6\eta - 3\eta^2)}{(2 - \eta)^2(4 - 2\eta - \eta^2)^2} (1 - \bar{\theta})^2
\]

\(^{35}\)The Mathematica code for all the computations in this Proposition are available upon request.
**A₁’s Welfare**

For agent A₁ the expected ex ante welfare without commitment can be written in terms of the cutoffs \((\bar{\theta}, \bar{\theta}_s)\) and the pooling action \(x^s_1 \equiv x^s_1(\bar{m}_p)\), and is given by,

\[
W^s_1 = - \int_{\bar{\theta}}^{\bar{\theta}_s} \left( \frac{x^s_1 + \eta x^s_2(\bar{m}_p)}{1 + \eta} - \theta \right)^2 f(\theta) d\theta - \int_{\bar{\theta}_s}^{1} \left( \frac{x^s_1 + \eta \bar{k}}{1 + \eta} - \theta \right)^2 f(\theta) d\theta
\]

\[
W^s_1 = - \int_{\bar{\theta}}^{\bar{\theta}_s} \left( \frac{1 - \eta}{\eta} ((1 + \eta)\bar{\theta}_s - \bar{\theta}) - (1 - \eta)\theta \right)^2 f(\theta) d\theta - \int_{\bar{\theta}_s}^{1} \left( \frac{1}{1 - \eta} \left( \frac{1}{(1 - \eta)} \bar{\theta}_s - \bar{\theta} \right) - \theta \right)^2 f(\theta) d\theta
\]

\[
W^c_1 = - \int_{\bar{\theta}}^{\bar{\theta}_c} \left( \frac{1 - \eta}{\eta^2} ((1 + \eta)\bar{\theta}_s - \bar{\theta})^2 + \frac{1 - \eta}{\eta} ((1 + \eta)\bar{\theta}_s - \bar{\theta})(\bar{\theta}_s + \bar{\theta}) - \frac{1 - \eta}{\eta^2} \left( \frac{1}{(1 - \eta)} \bar{\theta}_s - \bar{\theta} \right)^2 + \frac{1 - \eta}{\eta} \left( \frac{1}{(1 - \eta)} \bar{\theta}_s - \bar{\theta} \right)(1 + \bar{\theta}_s) - \frac{1 - \eta}{3} (\bar{\theta}_s^2 + \bar{\theta}_s + \bar{\theta}^2) - \frac{1}{3} (\bar{\theta}_s^2 + \bar{\theta}_s + 1)
\]

Substituting for the expressions and simplification yields,

\[
W^s_1 = - \frac{2}{3} \frac{(\eta^2 + 4\eta + 5)(1 - \eta)^2}{(4 - 2\eta - \eta^2)^2} (1 - \bar{\theta})^2
\]

With commitment,

\[
W^c_1 = - \int_{\bar{\theta}}^{\bar{\theta}_c} \left( \frac{x^c_1(\theta) + \eta \bar{k}}{1 + \eta} - \theta \right)^2 f(\theta) d\theta - \int_{\bar{\theta}_c}^{1} \left( \frac{x^s_1(\bar{\theta}_c) + \eta \bar{k}}{1 + \eta} - \theta \right)^2 f(\theta) d\theta
\]

\[
W^c_1 = - \int_{\bar{\theta}}^{\bar{\theta}_c} \left( \frac{1 - \eta}{\eta^2} (\theta - \bar{\theta})^2 f(\theta) d\theta - \int_{\bar{\theta}_c}^{1} \left( \frac{1}{\eta} \left( \frac{1}{(1 - \eta)} \bar{\theta}_c - \bar{\theta} \right) - \theta \right)^2 f(\theta) d\theta
\]

81
Simplifying this gives,

\[ W_c^1 = -\frac{(1 - \eta)^2}{\eta^2} \bar{\theta}^2 - \frac{(1 - \eta)^2}{\eta} (\bar{\theta} \bar{c} + \bar{\theta}) - \frac{(1 - \eta)^2}{\eta^2} \left( \frac{1}{(1 - \eta)} \bar{\theta} - \bar{\theta} \right)^2 + \frac{(1 - \eta)}{3\eta^2} \left( \frac{1}{(1 - \eta)} \bar{\theta} - \bar{\theta} \right) (1 + \bar{\theta}) - \frac{(1 - \eta)^2}{3\eta^2} (\bar{\theta}_c^2 + 2\bar{\theta}_c \bar{\theta} + \bar{\theta}^2) - \frac{1}{3} (\bar{\theta}_c^2 + \bar{\theta}_c + 1) \]

Expanding the terms \((\bar{\theta}, \bar{\theta}_c)\) and simplifying gives,

\[ W_c^1 = -\frac{2(1 - \eta)^2}{3(2 - \eta)^2} (1 - \bar{\theta})^2 \quad (29) \]

The gains from commitment for \(A_1\) is,

\[ G^1 = W_c^1 - W_s^1 = \frac{1}{3} \frac{(\eta + 2)(1 - \eta)^2(2 + 5\eta - 4\eta^2)}{(2 - \eta)^2(4 - 2\eta - \eta^2)^2} (1 - \bar{\theta})^2 \quad (30) \]

Since \(\frac{d\bar{\theta}}{dk} > 0\) and \(\frac{d\bar{\theta}}{db} < 0\), the statements in part (c) and (d) of the Proposition follow trivially from the expressions \(W_j^i\) and \(G^i\). This completes the proof. \(\text{QED}\)
